Introduction
Intraductal carcinoma of the prostate (IDC-P) is a term that refers to prostatic adenocarcinoma extending into and proliferating within preexisting prostatic ducts or acini (1). It is often associated with high-grade invasive prostatic adenocarcinoma and is also an adverse prognostic marker (1,2,3).

The histologic differential diagnosis of IDC-P on prostate needle biopsy includes high-grade prostatic intraepithelial neoplasia (HGPIN), invasive cribriform prostatic adenocarcinoma, prostatic ductal adenocarcinoma, and urothelial carcinoma extending into prostatic ducts. Diagnostic reproducibility is low in the category of intraductal lesions of the prostate (4) whereas, accurate diagnosis is crucial for patient management. When IDC-P is accompanied by invasive carcinoma, it is associated with higher grade and higher stage cancer. Isolated IDC-P (IDC-P unaccompanied by invasive cancer) on needle biopsy is generally associated with high-grade invasive prostatic adenocarcinoma on subsequent radical prostatectomy (2,4). IDC-P requires either definitive therapy or prompt rebiopsy. In contrast, HGPIN is considered a preneoplastic lesion; its presence does not require definitive therapy and in limited quantities, does not require rebiopsy. If urothelial carcinoma extending into prostatic ducts is identified on needle biopsy, radical cystoprostatectomy is recommended. Usual (acinar) prostatic adenocarcinoma and prostatic ductal adenocarcinoma are treated in the same manner and require definitive treatment.

Histologically, IDC-P is characterized by malignant epithelial cells filling and expanding nonneoplastic prostatic ducts and acini with at least partial preservation of an identifiable basal cell layer. Five patterns have been described: solid, dense cribriform, loose cribriform, micropapillary, and flat (rare). There is often marked nuclear atypia and frequent mitotic activity or comedonecrosis.

Intraductal spread of urothelial carcinoma is an important mimicker of solid IDC-P. Solid IDC-P is often associated with cribriform patterns elsewhere, which is not seen with intraductal spread of urothelial carcinoma (4). Greater nuclear pleomorphism, increased mitotic activity, and stromal inflammation favor intraductal spread of urothelial carcinoma (1). Furthermore, in intraductal spread of urothelial carcinoma, tumor cells are negative for prostate-specific antigen and prostate-specific acid phosphatase, and usually positive for p63 and high-molecular-weight cytokeratin.

The cribriform pattern of prostatic ductal adenocarcinoma is most likely to be confused with IDC-P. Prostatic ductal adenocarcinoma has cribriform glands with large, slit-like lumina, tall columnar tumor cells, papillary fronds with true vascular cores and usually lacks basal cells.

In conclusion, the differential diagnosis of intraductal lesions of the prostate on core needle biopsy is not always straightforward, but because of both therapeutic and prognostic implications, accurate diagnosis is crucial.
