**Abstract**

Transient osteoporosis of pregnancy is a rarely observed skeletal pathology developing in the last months of pregnancy. Meticulous evaluation is important for the differential diagnosis of severe and progressive hip and/or groin pain in pregnant patients. MRI is a valuable and safe technique for demonstrating bone marrow edema and skeletal abnormalities during pregnancy. Avoidance of vaginal delivery and non-weight bearing measures are essential in order to prevent complications such as hip fractures related to transient osteoporosis of pregnancy. We present the diagnostic evaluation and treatment of an uncommon case of transient osteoporosis of pregnancy with resolution of symptoms and postpartum.

**Case Report**

A 34 year-old, nulliparous woman had severe pain of increasing intensity in the right leg at 30 weeks of gestation. The pain was aggravated by getting up, sitting down and standing up. Clinical examination revealed mild pain without restriction of motion in the lumbar area. Abduction and external rotation of her right hip were limited by severe pain and she had an antalgic gait. The right lower segment of the abdomen was very tender to palpation at examination. She did not have any motor or sensorial deficit according to the neurologic examination. Lumbar discopathy was ruled out as a cause of the pain. Laboratory tests for electrolytes, thyroid function, rheumatoid factor and antinuclear antibody were normal. Magnetic resonance imaging (MRI) scans of the hips revealed alterations at the right coccygeofemoral junction consistent with transient osteoporosis accompanied by stress fracture (Figure 1). Joint aspiration was performed due to increased synovial fluid in the hip junction. She received analgesic treatment with paracetamol and nonsteroid anti-inflammatory drugs during pregnancy. During the remainder of the
pregnancy she was prescribed bed rest and avoided weight bearing. Cesarean section was recommended considering the risk of hip fracture during normal vaginal delivery. Calcitriol 0.5 mcg and calcium 1000 mg were prescribed soon after delivery. Whole body scintigraphy performed one month after delivery also demonstrated osteoporosis. Calcium 1000 mg, vitamin D3 880 IU and salmon calcitonin 200 IU/day, switched to alendronate 70 mg/week, were started for six months according to the scintigraphy findings. Her symptoms and MRI findings regressed 6 months following delivery (Figure 2).

Discussion

Physiotherapy, rheumatology and orthopedic consultations are considered for persistent, moderate to severe hip, back and/or groin pain during pregnancy. Pubic symphysiolysis, avascular necrosis, ostemyelitis, neoplasm and TOP should be ruled out in the differential diagnosis. Plain radiographs of the limb may demonstrate severe osteopenia for advanced cases of TOP. MRI is a more sensitive, safe and effective imaging technique for detecting skeletal abnormalities including TOP and hip fractures during pregnancy (5). Diffuse bone marrow edema by MRI, normal levels of markers for inflammation, severe and persistent groin and/or hip pain during the last months of pregnancy are positive findings for TOP. Prevention or permission for only limited weight bearing is essential in order to avoid complications in TOP. Atraumatic fractures may also be observed. Hip fracture is reported during labor; therefore cesarean section is preferred in cases with TOP (6). The palliative approach to TOP includes use of non-weight bearing measures such as bed rest, wheelchairs, crutches, analgesia and physiotherapy. Hips are usually remineralized within 6-14 months postpartum (7). Antiresorptive therapy with biphosphonates, calcium and vitamin D are used as adjunctive measures during the recovery period. In summary, TOP should be considered for the differential diagnosis of severe hip pain during pregnancy. Early diagnosis and treatment are essential in order to prevent its complications.
