Introduction

Cancer of the uterine cervix, in addition to local contiguous invasion, spreads mainly through local lymphatics. Local lymph nodes are commonly involved, meaning that distant metastasis is rare. Skin metastasis from cervical cancer is a very unusual event, particularly skin metastasis as a primary or recurrent presentation (as in the below-described case) of cervical cancer is very unusual indeed. Although cervical cancer is one of the commonest malignant neoplasms among Indian women-in fact, it is the commonest malignancy among women in rural parts of India (1)—skin metastasis from cervical cancer is extremely rare.

Case Report

A 60-year-old female was admitted to our Medical College with multiple swellings on the lower abdomen and inguinal region. This was associated with vague abdominal discomfort. On general examination she was cachectic; abdominal examination revealed a suprapubic scar and a nodular swelling over it. There were three swellings on the left upper thigh and inguinal region (Figure 1). Per vaginal examination showed a healthy vault.

Previous records revealed that she had been diagnosed with non-keratinising moderately differentiated squamous cell carcinoma of the cervix. One year previously she was admitted with a cervical growth which proved to be malignant and was in FIGO Stage IIa. The initial tumour size was approximately 4 cm at the largest diameter without any parametrial involvement. Routine work-up including chest X-ray and abdominal ultrasound did not reveal any para-aortic nodal or distant spread. She underwent Modified Radical Hysterectomy (Wertheim’s Operation). Histopathological examination from the post-operative specimen showed involvement of the bilateral internal iliac nodes. However, she did not receive any adjuvant therapy, although she was advised to do so, and she did not return for follow-up.

On this occasion, biopsy was taken from the skin nodules over the left upper thigh, which showed cutaneous deposits of metastatic squamous cell carcinoma. Excision biopsy from the swollen inguinal nodes also revealed deposits of squa-
mous cell carcinoma in the lymph nodes. She was diagnosed as a case of metastatic uterine cervical carcinoma, i.e. cervical cancer spreading to the skin and inguinal lymph nodes. Clinical and colposcopic examination revealed that the vaginal vault was free from tumour. Radiological investigations did not show the metastatic involvement of any other organ.

The patient was treated with six cycles of chemotherapy with Cisplatin (80 mg/m²) and Paclitaxel (225mg/m²; infusion over 3 hours) on day 1, every 3 weeks. She received the treatment according to the schedule. At the end of the chemotherapy course there was a 50% reduction in the size of the lesion and the enlarged lymph nodes disappeared. She received palliative radiotherapy of 3000-CGy external beam irradiation in 10 fractions over 2 weeks according to a conventional fractionation schedule. The lesions responded well to radiation therapy; however, four months later, she developed bilateral lung metastasis and died within three months. The period between the date of her presentation at our OPD with skin metastasis to the date of her death was seven month long.

Discussion

Metastatic carcinoma of the skin is an uncommon occurrence. Breast cancer is one of the most common primary tumours to metastasise to skin; gynaecological malignancies rarely give rise to metastatic deposits on the skin. Samaila et al. (2), from a search of twenty years institutional data from Nigeria, could find only four instances of cutaneous deposits from gynaecological malignancies, and in only one of these cases was the primary malignancy in the uterine cervix. Skin metastasis from uterine cervical carcinoma is a rare event. The reported incidence ranges from 0.1 to 2% (3).

To search PubMed for previously reported cases, we used the keywords “cancer cervix” and “skin metastasis”. All of the relevant literatures were thoroughly reviewed. Relevant cases are presented here in Table 1 (4-31). Studies dealing with cutaneous metastasis from all primary malignancies, among which some are from cancer of the cervix, are not included in Table 1 (3, 32, 33). Fifteen cervical cancer patients (out of 1190 patients) with skin metastasis from the study by Imchi et al. (34) are also not presented in the Table.

The most common sites of cutaneous metastases in cervical carcinoma are the abdominal wall and lower extremities (8). This is consistent with other carcinomas, in that metastatic spread to the skin is commonly located near the site of the primary tumour (33). The usual mode of spread has been suggested to be the lymphatic system (34). Imchi et al. (34), after reviewing 1190 patients with cancer of the cervix, including 15 of whom developed skin metastasis, observed that the incidence of skin metastasis was 0.8% in stage I, 1.2% in stage II, 1.2% in stage III, and 4.8% in stage IV. The incidence of skin metastasis seemed to be higher in patients with adenocarcinoma and undifferentiated carcinoma than in patients with squamous cell carcinoma. Macroscopically, three common patterns of skin metastases, such as nodules, plaques, and inflammatory telangiectatic lesions, have been recognised (33). Skin metastases from cervical carcinoma occur predominantly in cases of tumour recurrences, with metastases developing up to 10 years after the initial diagnosis and averaging less than 1 year (35). The prognosis associated with cutaneous metastasis of cervical carcinoma is poor. Usually, metastases to the skin occurring in patients with carcinoma of the cervix represent a pre-terminal event with a time from diagnosis to death of 3 months (3).

Systemic treatment in patients with advanced disease is palliative. Cisplatin is the single most active agent for the treatment of cervical cancer; however, recent evidence suggests that combination chemotherapy with cisplatin and paclitaxel may improve progression-free survival over the use of cisplatin alone (36). Palliative radiation is useful for controlling symptoms (37). The most important prognostic factor, in cases like this, is the time interval between the initial diagnosis of the primary genital malignancy and the appearance of skin metastasis, whether metastasis is isolated or as a part of more widespread systemic recurrence. The earlier the metastasis occurs, the worse the prognosis for the patient is. The intent of treatment remains palliation, either by radiation, chemotherapy or surgery (alone or in combination). Most of the previously reported cases had undergone some kind of surgical intervention for their disease, either radical surgical intervention or lymphadenectomy (in some cases laparoscopic lymph node dissection), before the disease was treated by radiation therapy or chemoradiotherapy. Careful handling of tissue dur-
ing operation, extension of radiation therapy portals to include the surgical scar and uncompromised primary treatment might prevent the development of skin metastases. Research targeted on the mechanism of local cancer spread and the interaction of cancer cells with the surgical wound environment may improve the knowledge regarding the pathogenesis of skin metastases and its clinical prognosis.

**Ethics Committee Approval:** Ethics committee approval was received for this study.

**Informed Consent:** Written informed consent was obtained from patients who participated in this study.

**Peer-review:** Externally peer-reviewed.

**Conflict of Interest:** No conflict of interest was declared by the authors.

**Financial Disclosure:** No financial disclosure was declared by the authors.
