Abstract

Objective: To compare the prevalence of various metabolic and cardiovascular risk factors and insulin resistance between polycystic ovary syndrome (PCOS) patients with or without hyperandrogenism.

Material and Methods: This is a retrospective cross-sectional study involving women with PCOS as diagnosed according to the Androgen Excess (AE) Society definition (n=504) and women with normoandrogenemic PCOS (n=183). Anthropometrics, lipid profile, glucose, insulin, oral glucose tolerance test (OGTT), and reproductive hormone levels were evaluated.

Results: Women with PCOS diagnosed according to the AE Society had a significantly higher prevalence of metabolic syndrome compared with the normoandrogenemic PCOS phenotype: odds ratio (OR) 2.95 [95% confidence interval (CI) 1.21–7.21]. There was no significant difference in the prevalence glucose intolerance test between the groups [OR: 2.15, 95% CI 0.71–6.56]. The prevalence of low high density lipoprotein (HDL)-cholesterol in the group under the AE-PCOS Society criteria was higher than that of the normoandrogenemic PCOS group [OR: 2.82, 95%CI 1.29–3.36].

Conclusion: The risks of metabolic syndrome and cardiovascular disease may vary among the phenotypes of PCOS based on the Rotterdam criteria. This new data may be of reference in informing women with PCOS, although further prospective studies are needed to validate this proposition. (J Turk Ger Gynecol Assoc 2016; 17: 201-8)

Keywords: Polycystic ovary syndrome, diagnostic categories, metabolic syndrome, hyperandrogenism, insulin resistance

Introduction

Polycystic ovary syndrome (PCOS) is a frequent endocrine abnormality of women in the reproductive period, and is related with infertility and menstrual irregularities (1, 2). PCOS is a heterogeneous condition, presenting with hyperandrogenism, polycystic ovarian morphology (POM), and oligomenorrhea (3-5).

The etiology of PCOS is elusive, but its long-term implications, including the risk of cardiovascular disease, type-2 diabetes mellitus, and endometrial carcinoma, are well known (6-8). However, PCOS is regarded as the most common endocrine abnormality of women in the reproductive period; its predicted frequencies vary in the literature, ranging from 2.2% to up to 26% (2, 9-12). A major reason for this variation is the absence of a consensus on the diagnostic criteria. Opinions differ on whether the presence of hyperandrogenism is an absolute requirement for a diagnosis of PCOS. The same holds true for the requirement of POM (13).

Chronologically, the National Institutes of Health (NIH) proposed the first diagnostic criteria. The NIH criteria required the combination of chronic oligo/anovulation and clinical or biochemical evidence of hyperandrogenism, with the exclusion of related disease (14). Subsequently, the Rotterdam European Society of Human Reproduction and the Embryology/American Society for Reproduction Medicine (ESHRE/ASRM) Sponsored PCOS (Rott-PCOS) Consensus Workshop group proposed the addition of POM to the NIH criteria, with a statement that PCOS could be diagnosed when any two of these three criteria were present (13). More recently, the Androgen Excess Society (AES) proposed new diagnostic criteria and stated that androgen excess is the sine qua non of PCOS and the syndrome must only be diagnosed in the presence of hyperandrogenism in combination with oligo/anovulation and/or POM (15).

Compared to the recent AES criteria, the Rotterdam criteria include an additional PCOS phenotype, comprising women with POM and oligo/anovulation in the absence of androgen excess. It is still unknown whether this new phenotype is also related to long-term health risks, such as metabolic syndrome, insulin resistance, and obesity (13, 16).
criticism (15). Although the normoandrogenemic PCOS phenotype appears to be weakly associated with adverse reproductive outcomes and metabolic syndrome compared with hyperandrogenemic PCOS, some evidence suggests that women with normoandrogenemic PCOS present with more severe insulin resistance (IR) and dyslipidemia (17-19). Whether women with only POM and oligo/amenorrhea bear similar metabolic and cardiovascular risks as compared with hyperandrogenemic women diagnosed with PCOS as per the AES criteria remains to be determined. This study aims to compare the prevalence of various metabolic and cardiovascular risk factors and insulin resistance between women diagnosed as PCOS with or without hyperandrogenism.

Material and Methods

This is a retrospective cohort study involving women who presented to our Gynecology Clinic between April 2011 and August 2012. The study protocol was approved by the Institutional Ethic Committee.

Demographic features and medical information regarding menstrual cycles, obstetric and gynecological history, and previous medication and/or disease were collected from the medical records. Body mass index (BMI) was calculated as body weight (in kilograms) divided by height (in meters squared). The waist to hip ratio (W/H) was calculated from dividing the waist circumference by the hip circumference.

A total of 1048 consecutive women diagnosed with PCOS were analyzed. PCOS was diagnosed with regard to the Rotterdam criteria, i.e., according to the existence of at least two of the following three features: 1) oligo- or amenorrhea; 2) clinical or biochemical hyperandrogenism; or 3) POM on pelvic ultrasound, after exclusion of other causes of hyperandrogenism, thyroid disorders, hyperprolactinemia, Cushing syndrome, and late onset congenital adrenal hyperplasia. Women with type-1 diabetes mellitus, hepatic or renal pathology, or receiving medication, which could affect carbohydrate metabolism or lipid profile, were also excluded. The follow-chart of subjects is presented in Figure 1.

Figure 1. The flowchart of subjects who attended the clinic
PCOS subtypes
The participants were divided into two groups: i) those fulfilling the AES criteria (n=504) (15) and ii) women with normoandrogenic PCOS (oligomenorrhea with POM; n=183). The criteria used to determine the components of the PCOS phenotypes were:

- Clinical hyperandrogenism was determined with a modified Ferriman-Gallewey score ≥8 (20).
- Biochemical hyperandrogenism was defined with the existence of at least one of the following findings: serum total testosterone level (TT) >65.82 ng/dL, serum dehydroepiandrosterone sulfate (DHEAS) level >374.9 µg/dL and free androgen index (FAI) >4.94 (calculated on the basis of the 95th percentile of basal serum androgen normality in the control group of 70 healthy, non-hirsute, eumenorrheic women from the same area (unpublished data).
- Oligomenorrhea was defined as having <8 menstrual cycles/year or menstrual cycles for more than 35 days.
- POM was defined with an antral follicle count (2–9 mm) of ≥12 in at least one ovary.

Definition of insulin resistance
Insulin resistance was predicted by using the homeostatic model assessment of insulin resistance (HOMA-IR) (21). The following formula was used to calculate HOMA-IR: (fasting insulin in µU/mL x fasting glucose in mg/dL)/405. A HOMA-IR value ≥3.8 was considered to represent insulin resistance (22). A 120-minute 75-g oral glucose tolerance test (OGTT) was done on a random day of the cycle. Impaired glucose tolerance test (IGTT) was defined by an abnormal glucose value following the 75-g OGTT, with cut-off values between 140 and 199 for 120 minutes. A value of 200 mg/dL or higher subsequent to 75-g OGTT were considered as diabetes mellitus type-2 (23).

Definition of metabolic syndrome (MetS) and dyslipidemia
The diagnosis of MetS was made in accordance to the definitions proposed by the National Cholesterol Education Program Adult Treatment Panel III (NCEP ATP III). Based on the NCEP ATP III, the diagnosis of MetS in women was defined by the presence of at least three of the following features: (i) waist circumference ≥88 cm, (ii) serum triglyceride (TG) level ≥150 mg/dL, (iii) serum high density lipoprotein (HDL) level <50 mg/dL or the previous consumption of lipid lowering medication, (iv) blood pressure ≥130/85 mmHg or the use of anti-hypertensive medication, (v) fasting blood glucose ≥100 mg/dL (24).

Dyslipidemia was diagnosed according to the definitions proposed by the Framingham/Adult Treatment Panel (ATP) III criteria (25). Regarding Framingham/ATP III, the diagnosis of dyslipidemia in women was defined by the following features: (i) low density lipoprotein (LDL-cholesterol) ≥130 mg/dL, (ii) HDL-cholesterol <50 mg/dL, (iii) triglyceride ≥150 mg/dL, (iv) total cholesterol (TC) ≥200 mg/dL, (v) TC/HDL ≥5.6.

Laboratory analyses
Comprehensive endocrine screening, including early follicular phase follicle stimulating hormone (FSH), luteinizing hormone (LH), total testosterone (TT), dehydroepiandrosterone sulfate (DHEAS), sex hormone-binding globulin (SHBG), thyroid stimulating hormone (TSH), and prolactin, was carried out. Plasma insulin, FSH, LH, SHBG, DHEAS, and TSH levels were analyzed by a chemiluminescence method (Immuliite 2000, Siemens Medical Solutions Diagnostics; Los Angeles, CA, USA). FAI was determined as follows: FAI = TT x 100/SHBG.

Fasting glucose and insulin, lipids, and carbohydrates levels were also determined. The plasma glucose, total cholesterol, HDL-cholesterol, and TG levels were tested by the spectrophotometric method (Abbott Trade C16000, Abbott Laboratories; Abbott Park, IL, USA). LDL-cholesterol and VLDL-cholesterol were calculated using Friedewald formulation. Highly sensitive C-reactive protein (hs-CRP) was analyzed by the nephelometric method (Siemens Dade-Behring BNII, Siemens Healthcare Diagnostics Inc.; Newark, BE, USA).

Statistical analyses
Continuous variables are defined herein with the mean ± standard deviation (SD), and categorical variables with numbers and percentages as appropriate. Baseline features of the different PCOS phenotypes were compared by independent samples t test. Proportions were compared using the chi-square test. Statistical significance was set at a two sided p value ≤0.05. The Statistical Package for Social Sciences (SPSS) was used for statistical analysis (version 19.0, SPSS Inc.; Chicago, IL, USA).

Results
Study population
The medical records of 8906 women were reviewed; 665 women were excluded due to inadequate data, including for unavailable data on the history of the cycle length (n=86), ultrasonographic examination (n=103), hirsutism (n=115), thyroid and/or prolactin laboratory assay (n=361). An additional 830 women were excluded due to the presence of concomitant pathology, including other relevant chronic diseases (n=165), congenital uterine anomalies and/or ovarian dysplasia (n=27), endometriosis (n=106), hyperprolactinemia (n=88), abnormal thyroid function (n=332), diabetes mellitus type-1 (n=4), premature ovarian failure (n=41), and the previous consumption of medications that may affect the carbohydrate pathway, lipid profile, or endocrine parameters (n=77) (Figure 1). The final study population included 687 women diagnosed with PCOS based on Rott-PCOS criteria. While 504 of these women met the AES-PCOS criteria, 183 women were classified as normoandrogenic PCOS. The prevalence of different PCOS phenotypes is presented in Table 1.

The prevalence of women with clinical and/or biochemical hyperandrogenism, oligomenorrhea (OM), and POM was 7.6, 8.5, and 7.1%, respectively. Demographic characteristics, and the biochemical and anthropometric features of the participants are presented in Table 2. There were no differences among the PCOS subgroups regarding age (p=0.62; Table 2). The mean concentration of C-reactive protein (CRP) in women diagnosed as PCOS according to the AES criteria was significantly higher that of women classified as normoandrogenic PCOS (5.96±6.92 vs. 4.21±3.12 mg/L, p=0.003).
Prevalence of insulin resistance

A comparison of the data between AES-PCOS and normoandrogenic PCOS revealed a significant difference for the carbohydrate traits assessed, including HOMA-IR (p=0.004), fasting insulin (0.007), and fasting glucose (p=0.001).

The overall prevalence of elevated fasting blood glucose and insulin resistance among the PCOS patients was 17.8% and 31.7%, respectively. While the rates of elevated blood glucose and insulin resistance were 19.9% and 32.8% in the AES-PCOS group, within the women classified as normoandrogenic PCOS, these rates were 10.0% and 26.3%, respectively (p=0.01 and 0.34, respectively). The respective odds ratios for insulin resistance in patients diagnosed as PCOS according to the AES criteria was 1.36 [95% confidence interval (CI), 0.77–2.58] when compared with the subjects classified as normoandrogenic PCOS (Table 3).

AES: Androgen Excess Society; n: the number of women available for each characteristic measured; HOMA-IR: homeostatic model assessment of insulin resistance; HDL-cholesterol: high density lipoprotein; LDL-cholesterol: low density lipoprotein; VLDL-cholesterol: very low density lipoprotein

Data are expressed as the mean±SD unless otherwise was stated.

*Statistically significant (p<0.05).
The prevalence of IGTT was 19.9% in the whole PCOS population. In the AES-PCOS group, 31 of 146 patients (21.2%) had impaired glucose tolerance during OGTT and of these, two patients had DM type 2 (1.4%), while the prevalence rate for the abnormal glucose tolerance test in the normoandrogenic PCOS group was 11.1% (p=0.23). The respective odds ratio for the glucose intolerance test in patients diagnosed as PCOS according to the AES criteria was 2.15 [95% CI, 0.71–6.56] when compared with subjects classified as normoandrogenemic PCOS.

Prevalence of MetS and dyslipidemia

While the overall rate of metabolic syndrome in women with PCOS was 22.5%, within women diagnosed as PCOS according to the AES-PCOS criteria and normoandrogenic PCOS, these rates were 25.4 and 10.3%, respectively (p=0.01; Table 3). The respective odds ratio for MetS in women with AES-PCOS was 2.95 [95% CI, 1.21-7.21] when compared with subjects classified as normoandrogenic PCOS. The distribution of the components of metabolic syndrome is also presented in Table 3. Regarding the lipid profile, the concentrations of HDL-cholesterol, TG, TG/HDL-cholesterol ratio, and VLDL-C were significantly different in women with AES-PCOS from the subjects with normoandrogenic PCOS (p=0.004, p=0.03, p=0.002, and p=0.02, respectively; Table 2). The prevalence of low HDL-cholesterol in the group under the AE-PCOS Society criteria was higher than that of normoandrogenic PCOS (59.4 vs 41.2%, respectively; p=0.002; Table 3), while the prevalence of low HDL-cholesterol was 56.1% in the whole study group. While the prevalence of elevated total cholesterol (≥200 mg/dL) and LDL-C (≥130 mg/dL) parameters in the whole population were 18.3 and 14.6%, respectively, there were no statistically significant differences between women diagnosed as PCOS according to the AE-PCOS Society criteria and women with normoandrogenic PCOS (18.6% vs. 17.2% and 15.2% vs. 11.6%; p=0.77 and p=0.39, respectively). While the prevalence of elevated TG (≥150 mg/dL) was 21.5% in the whole study group, within the patients diagnosed as PCOS according to the AE-PCOS and normoandrogenic PCOS, these rates were 23.0 and 14.9%, respectively (p=0.09). While the prevalence of elevated TC to HDL-cholesterol ratio (≥5.6) in the whole population was 7.6% within women diagnosed as PCOS according to AE-PCOS, this rate did not differ from subjects with normoandrogenic PCOS (8.5 and 3.5%, respectively; p=0.12).

Discussion

In the current study, the prevalence of PCOS according to the Rotterdam and AE-PCOS Society criteria in a Caucasian population were 9.3 and 6.8%, respectively. Although the results of the current study are in concurrence with the previously reported frequency’s ranging from 11.2 to 20.9% according to the Rotterdam criteria (18, 26-28), we found lower figures than a prior Turkish cohort study using the AE-PCOS Society criteria (18).
Further, data from this study illustrated that the prevalence of insulin resistance and impaired glucose tolerance barely rise in the overall PCOS population (31.7 and 17.8%, respectively) when compared to that reported from another study of Turkish women with PCOS (29). This study has also shown that women with PCOS have a higher prevalence of metabolic syndrome (22.5%) than that consistently reported from the literature, albeit with a varying rate (17, 18, 28).

Although there is limited data on the association of the new phenotype (normoandrogenemic PCOS) and its implications on the metabolic profile, it has been reported that the normoandrogenemic PCOS phenotype has a milder metabolic syndrome with a rather similar rate of insulin resistance (30). The evidence currently suggests that patients with PCOS diagnosed according to AE-PCOS Society criteria have the most severe metabolic features (15, 17). Women in PCOS without hyperandrogenism are still the subject of debate (2, 15, 16). The Androgen Excess and PCOS Society suggested that PCOS initially should be accepted as a condition of hyperandrogenism (15). The current study demonstrated that in women diagnosed according to AE-PCOS Society criteria, the proportion of increased serum glucose level was double in comparison with that in women identified as normoandrogenemic PCOS, while the rate of women with an abnormal glucose tolerance test and insulin resistance rose by almost 10%. These findings appear to support the previous observations that women with normoandrogenemic PCOS exhibit a small proportion of hyperglycemia and insulin resistance (31, 32).

An impaired lipid profile is a prevalent finding in women with PCOS (33, 34), and also it was recently noted that the TG, LDL-cholesterol, and TC levels are significantly higher in obese PCOS women than in lean/normo-weight PCOS women, irrespective of the PCOS phenotypes (35). Women with hyperandrogenic PCOS showed the most atherogenic lipid profiles, with higher apolipoprotein B compared to the other PCOS phenotypes (36). However, conflicting data are present in the literature. Moreover, despite the similar rate of IR in BMI-matched PCOS phenotypes, free testosterone and FAI were positively correlated with triglyceride as well as being inversely correlated with HDL-cholesterol (37). Conversely, other researchers speculate that lipid abnormalities are not different in women with hyperandrogenic PCOS (38, 39). In accordance with the previous study, we also observed that women with normoandrogenic PCOS have a lower triglyceride/HDL-cholesterol ratio, triglyceride, and VLDL-cholesterol concentrations as well as higher HDL-cholesterol levels when compared with those of women diagnosed as PCOS according to the AES-PCOS criteria, although BMI was not significantly different between the PCOS phenotypes (37). These findings suggest that hyperandrogenemia may adversely affect the lipid metabolism regardless of the presence of MetS or IR. However, the higher prevalence of decreased HDL-cholesterol with a similar rate of elevated TG, total cholesterol, and LDL-cholesterol observed in this study may indicate the effects of insulin resistance on HDL-cholesterol. Further, this finding would be an indirect reflection of increased ovarian androgen secretion in women with PCOS, as proposed in previous reports (40, 41).

According to the new diagnostic criteria (2, 13), PCOS may de facto involve a large-scale number of abnormalities, consisting of women with mild clinical and hormonal abnormalities (42, 43). As regards metabolic syndrome (evaluated with the International Diabetes Federation criteria), our cohort study showed a proportion of 22.1% had it in the overall PCOS population according to the Rotterdam criteria consistent with a previous cohort study in a Mediterranean population (44). Furthermore, women diagnosed with PCOS according to the AE-PCOS Society criteria had a higher rate of MetS than those with normoandrogenic PCOS (20.4 vs 9.2%). This significant difference is in line with previous studies (45-48). The explanation for this quite pronounced difference may be that the key features of MetS comprising abdominal obesity, insulin resistance, and impaired glucose tolerance are present less frequently in normoandrogenic PCOS (24). Indeed, a current meta-analysis showed that elevated serum androgen levels have a positive correlation with the prevalence of MetS (49).

Overall, women with normal androgen levels appear to be part of the milder PCOS spectrum, but this might be due to the less frequently elevated blood glucose level, which is related with lower health-risk-related factors.

It has also been found that subclinical atherosclerosis expressed as low-grade inflammation (increased hs-CRP levels) could be a factor for an increased risk of cardiovascular disease and DM type 2 in women with PCOS (50-52). Moreover, an elevation in circulating hs-CRP irrespective of obesity is evidence that chronic low-grade inflammation may have an effect on the pathogenesis of PCOS, particularly in hyperandrogenic phenotypes (4, 53). In accordance with previous reports, we also observed a significant elevation of hs-CRP in women with hyperandrogenemia compared to women with normal androgen levels, despite there being no difference in BMI between the phenotypes (4, 53). This assumes that a high androgen level independently may be a factor that affects the establishment of cardiovascular disease in women diagnosed as PCOS.

Limitations for the study include that the methodology of study was a retrospective cohort, and also the numbers in the normoandrogenic PCOS group were too small to assess the statistical significance for the oral glucose test intolerance. In conclusion, women with hyperandrogenic PCOS usually present an impaired lipid profile, insulin resistance, and abnormal glucose tolerance, which may be related to the subsequent development of MetS. PCOS patients with androgen excess appear to be exposed to a higher risk of cardiovascular disease than normoandrogenic PCOS patients (54, 55).

The observations of the present study suggest that the androgen excess per se is related with a long-term-health-risk of PCOS. This new data may be of reference in informing women diagnosed as PCOS, even though further prospective studies are needed to validate this proposition.
