Oral Ibuprofen Induced Spontaneous Intestinal Perforation in a Preterm Infant

Preterm Bir Beekte Oral Ibuprofenin İndüklediği Spontan İntestinal Perforasyon

**Introduction**

Spontaneous intestinal perforation (SIP) of the newborn is a single intestinal perforation, characteristically present at the terminal ileum and usually consists in low birth neonates or babies who receive corticosteroid treatment early in life (1-4). We present a case of a preterm neonate with spontaneous intestinal perforation induced by oral ibuprofen treatment for PDA.

**Case Report**

Twin babies of a Syrian mother without antenatal follow-up were born via cesarean section at the 27th week of gestation. One baby was 1250 grams at birth with an Apgar score of 5 in the first minute. He was intubated and transferred to neonatal intensive care unit (NICU) for respiratory distress. Total parenteral nutrition as well as minimal enteral feeding with breast milk was started on the admission day. On follow-up, oral intake was increased to 20 cc/kg/day and total parenteral nutrition was decreased accordingly. He reached his birth weight on the 7th day of admission and as enteral feeding was well-tolerated, on day 10, full enteral feeding was initiated. He was referred to a pediatric cardiologist for a cardiac murmur detected in routine physical examination and diagnosed with PDA. Therefore, oral ibuprofen treatment was started on day 3. The condition of PDA was outlined by the presence of a minimum of one amongst the subsequent criteria: internal ductal diameter ≥1.5 mm, left-atrium-to-aortic-root ratio >1.6 nonrestrictive, pulsatile transdural flow, reverse or absent diastolic flow within the aorta. On day...
was discontinued on the 10th day. As control acute phase showed grade 1 retinopathy of prematurity. Vancomycin grade 3 intraventricular hemorrhage. Ophthalmic examination showed no pathology except thrombocytopenia and anemia. Cultures turned out to be negative, and laboratory results showed no pathology except thrombocytopenia and anemia. Treatment was continued. Cranial ultrasonography revealed recurrent high fever episodes during follow-up, though blood cultures confirmed the suspected fungal sepsis. The patient received no financial support.

Discussion

Gastrointestinal side effects related to ibuprofen are mostly known to occur within the first days of life, late occurrence is rare. In our patient, although full enteral feeding was initiated earlier, abdominal distention developed on the 11th day after birth, without any risk factors or other warning signs of NEC, like nausea or feeding intolerance. Therefore, SIP related to ibuprofen use was the initial diagnosis.

SIP of the newborn is typically found at the terminal ileum (1-5). SIP happens especially in premature infants with very low birth weight (<1500 g), and extremely low birth weight (weight <1000 g). SIP is a different clinical entity from NEC, the most severe gastrointestinal complication in premature infants (1,6,7).

In our case, the patient was in the high-risk group as his birth weight was 1210 grams at the 27th gestation week. Our case had no antenatal history of chorioamnionitis.

In a study from the Pediatrix bunch, the organization of antenatal glucocorticoids did not seem to expand the danger of SIP (8). Early organization of postnatal glucocorticoids expands the danger of SIP. However, our case did not receive postnatal or antenatal glucocorticoid treatment (9). In spite of the fact that the postnatal utilization of indomethacin had been already answered to build the danger of SIP, ensuing productions have reported no relationship between indomethacin introduction and SIP (9,10).

NEC normally develops after the first week of life, after the baby has started to bolster, whereas, in our case abdominal distention was detected on the 11th day after birth, long after the initiation of full enteral feeding. Abdominal radiographic images might reveal pneumoperitoneum, however, in our case there was no sign of pneumatosis intestinalis or portal venous gas, which are the radiograph signs of NEC. Imaging exhibits a gasless stomach area in a few patients with SIP. The average age at aperture placement is seven days with a scope of 0 to 15 days. SIP generally starts earlier than NEC. (mean age; 7 vs. 15 days) (8).

Hazard elements for SIP might fluctuate as per the season of presentation. In a Pediatrix investigation of 633 neonates with SIP the patients were divided into two based upon their time of presentation (10) as newborn children in the main group (n=116), somewhere around zero and three days of life, who were bigger (middle birth weight 1.4 kg) and were less inclined to have gotten antenatal glucocorticoids, indomethacin, surfactant, or mechanical ventilation, and babies in the second group, around 7 and 10 days of life with a mean birth weight of 776 g. In our report, the baby weighed 1210 grams, which is compatible with the second group.

Current treatment of choice for SIP is surgery. Exploratory laparotomy with the resection of the bowel or primary peritoneal drainage (PPD) are the traditional approach. In a previous study, PPD and exploratory laparotomy were compared in the newborns diagnosed with either SIP or NEC, and no difference was found in mortality or prognosis between the two groups (11). In our case, we used exploratory laparotomy with bowel resection in addition to ileostomy and colostomy.

In conclusion, oral ibuprofen treatment for PDA closure may increase the risks for the immature gastrointestinal system. Therefore, intravenous route may be the safer choice for preterm infants.
