ABSTRACT

Aim: Burns are still an important mortality and morbidity problem worldwide. Clinical studies are limited, owing to ethical concerns and an inability to achieve standardization. Therefore, studies are concentrated on experimental models. However, there are still a lot of questions that await resolution. Additionally, the relevance of animal models on human skin (HS) is unknown. From this point of view, this study aims to evaluate the depth of burn on ex vivo HS and to compare the HS results with those of rats.

Materials and Methods: Skins of patients, after obtaining informed consent, that underwent full thickness healthy skin excision (abdominoplasty), except for experimental purposes, have been included. A total of three different temperatures (60, 80 and 100 °C) using two different weight forces (0.88 kg/cm² for high and 0.21 kg/cm² for low) using standardized apparatus facilitated the formation of study groups. In all groups, healthy dermis-epidermis burn depth was compared.

Results: No difference was detected between healthy HS depths from the various samples taken from different donors that were to be tested. The lowest result (10.5±0.7% burn depth) was seen in the 60 °C low weight force group and the highest was seen in the 100 °C high weight force group (92.0±2.7). As for the 80 °C high pressure group vs the 100 °C low pressure groups, a significant difference was noted.

Conclusion: Ex vivo HS can be used as an experimental burn model. It has been shown that standardized depth of burn can be achieved using standardized apparatus. However, the different depth of burn indicates that control of parameters (pressure, time, temperature) is mandatory.

Keywords: Burn, ex vivo, human skin, rat

Introduction

Burns are still a frequent trauma worldwide. According to the American Burn Association statistics, between 2006-2015, 205.033 individuals have suffered from burn trauma and 3.3% of them lost their lives (1,2). Since the mid-20th century, owing to numerous experimental or clinical studies, treatment modalities have been improved. However, due to ethics and standardization problems in clinical studies, experimental studies have been mostly preferred for physiopathology and healing procedures (3-9). Therefore, various scalding and contact burn models have been defined.
However, infeasible real-time contact temperatures and applied weight force (WF) measurements were the weak points of these models (3,14). For this reason, in 2016 we designed a standardized contact burn model in which the real-time contact temperature and pressure could be controlled (15). A standardized second degree burn can be achieved in rats using custom designed apparatus (15). However, although the created wounds were second degree, the burn percentages were significantly different from each other. Moreover, an experimental model on human skin (HS) that defines the degree of burn has not been put forward before. With this goal in mind, this study aims to answer the following questions:

- What will be the degree of burn depth under the standardized experimental burn model?
- What are the responses and nuances of rat and HS in a standardized burn model?

**Materials and Methods**

This study has been conducted following approval by the human Ethics Committee (approval number: 20/02/2017-80558721/71) of Eskişehir Osmangazi University. HSs, which were assessed as waste material, were obtained from the discarded tissue of patients undergoing abdominoplasty. Before surgery informed consent was obtained from all individuals. Following excision in the operating theatre, skins were wrapped in the fresh frozen plasma (FFP) soaked gauze; transported in a vacuum bottle at +4 °C and kept at +4 °C until the end of procedure. All experimental steps (burns and biopsy) were performed on the same day (0 day following excision). Custom designed apparatus was used for the ex vivo HS model (Figure 1). Three temperature groups (60, 80 and 100 °C) and two WF groups were designed, while the elapsed time was set at 10 sec. in all groups. The burns were created using two levels of pressure upon the skin sample, with light contact being applied for the first group, defined as the Low WF group (LWFG), and 1.000 gr of WF being applied for the second group, defined as the High WF group (HWFG). However, real time WF force was measured in all burns due to a spring-loaded design of apparatus. Healthy normal skins of all individuals were used for a control group to measure dermis and epidermis thicknesses (Figure 2).

LWFG: Low weight force group, HWFG: High weight force group

Slices were stained with hematoxylin eosin and examined by a blinded anatomist under light microscopy (Nikon) (Figure 4). Photographs of the burns were taken. Skin thicknesses (dermis, epidermis) and burn depths were measured from three different lines (Figure 4). Mean values and burn ratios (burned/healthy skin) were calculated for each wound using the Microsoft Excel program. Graphpad Prism 7 software was used for statistical analysis. The normality distribution of the data was assessed by the Shapiro-Wilk test. Groups were compared using a Two-Way ANOVA test with a post hoc test of Tukey’s multiple comparisons. P values less than 0.05 were considered as statistically significant.
**Results**

The discarded healthy skin of 4 patients were used. No difference was detected in the *ex vivo* healthy HS (dermis and epidermis) thickness of the patients (p>0.05). A mean of 0.21 kg/cm² WF was applied in the LWFG and 0.88 kg/cm² in HWFG. In addition, neither in the LWFG nor in the HWFG was any difference detected (p>0.05). The percentage of burns is given in Table I. Comparing the G80HWFG vs G100LWFG groups, highly significant different depth of burns was noted between them (p<0.001). Furthermore, on *ex vivo* HS, in case of LWF force at 60 °C, first degree burns could be created; superficial second-degree burns could be achieved if HWF is applied at the same temperature. Borderline superficial/deep second-degree burns were detected in the G80LWFG. Deep second-degree burns were confirmed in both the G80HWFG and G100LWFG groups. Third degree burns were ascertained in the G100HWFG group (Figure 3, 4).

**Discussion**

Burns are the most frequent trauma with an incidence of 1.1/100,000 worldwide (2). According to trauma statistics, burns are the underlying reason for approximately 5% of the patients who lose their lives due to trauma worldwide (1,2). Therefore, studies concerning burns have being on to evaluate prevention, physiopathology and treatment modalities. Cetin et al. (16) compared the survival of *ex vivo* HS in FFP soaked gauze and saline. And found that HS lives on in FFP for approximately thirty days. Therefore, all study procedures were performed in day 0 following excision as it is believed that results of the study would best simulate a living HS contact burn wound. Thus has not been reported on previously. Consequently, *ex vivo* HS and a custom designed standardized contact burn model have been used to depict the depth of burn on HS in a controlled manner. It was hoped that this study could provide a basis for a new experimental model on HS. What’s more, this study could be helpful in understanding the correlation between temperature and WF on HS.

Herein, this study has shown that different statistically significant depths of burn, from 10.5% to 92% under a strict control of variables (time, temperature and WF), on *ex vivo* HS. In comparison to the animal model, more superficial burn depths have been noted on *ex vivo* HS, although there was no difference between the steps of experimental model (15). And it was realized that for Groups 1 and 6, variable depths of second degree burns were created as in the animal model. Moreover, they all have significantly different percentages of burn wounds from each other such as superficial, borderline deep/superficial and deep second degree. This might be due to different skin thicknesses or might suggest that HS is much more resistant than the skin of the rat. Finally, we believe that such different percentages of burns might cause variable inflammatory responses and that might affect the healing capacity as well. Hence, this might play an important role in inflammatory and/or healing procedures that should be evaluated.
Study Limitations

The ex vivo nature of the study—that is without a blood supply—is its limitation. Although the skin is alive, it is impossible to account for immune reactions and put forward treatment studies. This model could be extended to become the basis for cell culture studies.

Conclusion

Due to custom designed apparatus, standard depth of burn on ex vivo HS could be investigated. The percentage of burn depth changes according to accurately controlled variables (time, WF and temperature) during the contact burn ex vivo HS has been presented. As a result, variables should be strictly under control. Especially for experimental healing models, for standardization of burns, percentage of burns might be a better indicator for classification.

Acknowledgement

Authors would like to thank to Mr. İlhan Şesan (retired technician) for his contribution in designing the burn apparatus.

Ethics

Ethics Committee Approval: The study was approved by the Eskişehir Osmangazi University Local Ethics Committee (approval number: 20/02/2017-80558721/71).

Informed Consent: Consent form was filled out by all participants.

Peer-review: Externally peer-reviewed.

Authorship Contributions

Conflict of Interest: No conflict of interest was declared by the authors.

Financial Disclosure: The authors declared that this study was funded by Eskişehir Osmangazi University Scientific Research Foundation.
