Multifocal Synchronous Chromophobe, Papillary, and Clear Cell Renal Cell Carcinoma in a Single Kidney

We present a unique case of concurrent chromophobe, clear cell, and papillary renal cell carcinomas (RCC) in three separate sites in the same kidney after partial nephrectomy. We review the literature of synchronous RCC of up to two histologic subtypes, which is rare in occurrence.

Keywords: Chromophobe, Clear cell carcinoma, Papillary, Partial nephrectomy, Renal cell carcinoma

a 2.2 cm mildly dense lesion (29 HU) in the anterior superior pole suggestive of a hemorrhagic/proteinaceous cyst. In the mid to lower pole, there were two adjacent, mildly dense, largely homogenous lesions with no discernable contrast enhancement. The posterior lesion was 4 cm and exhibited near-fluid attenuation with no enhancement, compatible with a cyst. The anterior lesion was 3.1 cm with mildly increased density (26 HU) and no significant contrast enhancement (32 HU) suggestive of a hemorrhagic/proteinaceous cyst. A bone scan was negative for metastasis.

After extensive discussion, the patient elected to undergo robotic partial nephrectomy of the solid anterior interpolar mass. The other lesions were thought to be benign cysts that did not warrant excision. However, at the time of surgery, while exposing the solid tumor, the lower pole lesion was identified and it appeared to be a complex cystic mass, concerning for malignancy. Thus, both tumors were excised separately. There was a simple cyst in the upper pole that was decorticated and the cyst wall was sent for pathologic examination. All three lesions were removed with a total warm ischemia time of 27 minutes. The remainder of the surgery was unremarkable. He was discharged home on postoperative day two.

Pathologic examination revealed multiple histologic subtypes of RCC. The solid tumor in the interpolar region was composed of eosinophilic cells that were positive for CD117, showed membranous staining for cytokeratin 7 and focal positivity for vimentin, supportive of the diagnosis of eosinophilic variant of chromophobe RCC (Figure 2A). The lower pole tumor was morphologically a papillary RCC, supported by diffuse positive staining for racemase (Figure 2B). The upper pole cyst was a cystic clear cell RCC (Figure 2C). The neoplastic cells were positive for keratin AE1/3, paired box gene 8 and vimentin, with a Fuhrman nuclear grade of 1. All margins were negative.

The patient was seen in follow-up six weeks postoperatively, doing well with excellent renal function. Given such rare pathology and multifocality, the patient may be at higher risk for recurrence. He will be followed with a magnetic resonance imaging three months postoperatively.

Written informed consent was not required at our institution for case report. Patient is not identified.

Discussion

Synchronous renal tumors of varying pathology in the same kidney is a rare phenomenon. There have been reports of concurrent RCC and benign tumors such as oncocytoma and angiomyolipoma (AML) as well as other primary malignancies such as adrenal (1,2). To our knowledge, this is the first report of multifocal RCC with synchronous tumors of three different histologic subtypes in one kidney: chromophobe, clear cell, and papillary.

There have been only a few case reports of two synchronous RCCs appearing in the same kidney. Na et al. (3) reported a case of an adult patient with autosomal dominant polycystic kidney disease on hemodialysis who was found to have multiple...
lesions of both papillary and clear cell RCC in the same radical nephrectomy specimen. The patient had no evidence of disease at three-month follow-up. Synchronous chromophobe and papillary RCC has been reported in a solitary kidney with two distinct masses (4). Interestingly, Roehrl et al (5) described a patient with a single 5 cm renal mass that was found to have components of chromophobe and papillary RCC. Three months after radical nephrectomy, the patient was without evidence of disease.

There have been few reports of synchronous RCCs with AML. Jun et al. (6) reported a radical nephrectomy specimen containing separate lesions including chromophobe RCC, clear cell RCC, and AML. Similarly, Kang et al. (7) reported synchronous chromophobe RCC, clear cell RCC, and an AML in a 62-year-old woman with tuberous sclerosis, who was healthy and without evidence of recurrence six months postoperatively.

The natural history and prognosis for a patient with multiple synchronous RCC lesions of varying subtypes are unknown, given its inherently rare nature. Moreover, the follow-up period of 3-6 months for the patients with two subtypes of RCC in these previously mentioned case reports is short and information about long-term outcome is lacking. All reported patients were treated with radical nephrectomy for multiple tumors. Our patient was treated with partial nephrectomy and found to have negative margins. Our patient may have a potential for worsened prognosis or even a higher likelihood of recurrence given three synchronous types of RCC. However, since the patient underwent a partial nephrectomy and has excellent renal preservation, the choice of adjuvant therapy is not limited by renal function.

In conclusion, the occurrence of multiple, synchronous, ipsilateral renal neoplasms including chromophobe, clear cell, and papillary RCC is rare and prognostic information is not widely available. Thus, careful monitoring and close follow-up of such patients is critical.
