**Keywords:** Acne vulgaris, psychosocial aspects, quality of life

Acne vulgaris is one of the most common diseases affecting the quality of life among skin diseases (1). Studies have shown that patients with acne have high rates of depression, anxiety, suicidal tendency, and negative effects on quality of life have generally been shown to increase with increased acne severity (2). Motley and Finlay (3) from Cardiff University developed “Cardiff Acne Disability Index” (CADI) specifically for patients with acne vulgaris. This index evaluates the findings of how the patient was affected physically, psychologically, emotionally, and socially due to illness. The Turkish version of the CADI form was used in our study (4).

Global Acne Grading System (GAGS), which is used to evaluate clinical severity, is one of the most commonly used scoring systems (5). The study was started following local ethics committee approval (dated 15/12/2016, number: 135).

A total of 202 patients (13-45 years old, 133 female and 69 male) with acne vulgaris were included in the study. Seventy-six patients were under 18 years old and 126 patients were 18 years or older. The mean value of CADI was 6.8±3.0 in all patients, 7.1±3.0 in females and 6.1±3.1 in males. These results showed that CADI was significantly higher in females than males (p=0.033). The mean overall CADI score was 6.3±3.0 in female patients under 18 years of age and 7.5±3.0 in female patients 18 years or older (p=0.035). The mean overall CADI score was 6.6±2.9 in male patients under 18 years of age and 5.7±3.1 in male patients 18 years and older (p=0.184).

The question indicating how the patient perceived his psychological condition had the lowest mean value with a score of 1.9±0.8 and the question asking for the negative emotions and psychological status of the patient due to acne vulgaris was significantly higher in females (mean: 1.5) than in males (mean: 1.2) (p=0.017). Also, the mean score of the question showing how the patient perceived the disease was significantly higher in females (mean: 2.0) than in males (mean: 1.7) (p=0.028). These results showed that women perceived their illness as more severe. The mean score of the question on the negative effects of acne lesions on social life was significantly lower in females under 18 years of age than in females 18 years or older (0.7 vs. 1.1, respectively, p=0.017). There was no significant difference between individual questions in terms of gender and age.

There was no significant correlation between age and GAGS score in all patients and in only female patients (p=0.183, p=0.214, respectively). However, GAGS score was significantly higher in male patients under 18 years of age than those aged 18 years and older (p=0.045).

Men had more severe acne vulgaris than women. Regarding age, male patients under 18 years of age had more severe acne vulgaris lesions compared to male patients aged 18 years and older and female patients.

There was no significant correlation between GAGS score and overall CADI score and individual question scores (p=0.218).

Although the severity of acne vulgaris in females was less than in males in this study, it was found that their quality of life was negatively affected and that CADI scores were significantly higher than males. While CADI score was significantly lower in females under 18 years of age than in females 18 years and older, there was no difference in males in terms of age.
Questionnaire score regarding the effects of acne vulgaris lesions in the body was found to be low in our study. Unlike other studies, the question asked in order to reveal how a person perceives his or her own disease psychologically has the highest mean value in all patients.

In conclusion, although the GAGS score was higher in male patients and males had more severe acne lesions clinically, it was found that female patients were more affected psychologically and that this effect was more prominent especially in women aged 18 and over regarding CADI scores.
