Non-hodgkin Lymphoma Developing After Discontinuation of Direct-acting Antiviral Treatment for Hepatitis C: A Case Report

Hepatitis C’s Direk Etkili Antivirallerle Tedavisinden Sonra Gelişen Non-hodking Lenfoma: Bir Olgu Sunumu

ABSTRACT

Today, direct-acting antivirals (DAA) are the main treatment options for hepatitis C infection. However, whether malignancy risk is increased after DAA treatment is a matter of debate. Conflicting results have been reported in the relevant studies. In this paper, we present the case of B-cell non-Hodgkin lymphoma developing after DAA treatment in a patient with complete response to hepatitis C treatment.

Keywords: Hepatocellular carcinoma, hepatitis C, non-Hodgking B cell lymphoma

ÖZ

Günümüzde doğrudan etkili antiviraller (DAA), hepatit C enfeksiyonu için ana tedavi seçenekleridir. Fakat DAA tedavilerinden sonra, hastalarda malignite riskinin artırıldığını gösteren olgu sunumları vardır. Bu sunumda DAA tedavisi sonrasında tam cevap elde edilen bir hastada tedaviden sonra gelişen B hücreli non-Hodgkin lenfoma ve arasındaki deneyimin paylaşıldığı amaçlanmıştır.

Anahtar Kelimeler: Karaciğer karsı, hepatit C, non-Hodgking B cell lenfoma

Introduction

The frequency of side effects associated with direct-acting antiviral (DAA) treatment is very low compared to interferon-based treatments (1). Currently, sustained virological response (SVR) has increased significantly with the use of DAA in hepatitis C treatment. More than 95% of patients have a SVR after DAA-based treatment (2). Moreover, even patients with decompensated cirrhosis may become treatable after treatment with DAA.

The targeting of new antiviral drugs directly to hepatitis C virus (HCV) replication allowed very high response rates compared to old regimens, regardless of the stage of liver fibrosis. Currently, more than 95% of patients have a SVR after DAA-based treatment (2). However, there have been a few reports of occurrence of malignancy in patients previously treated with DAAs (3,4). In a multi-center study from Spain with 58 patients and in a single center study with 59 patient from Italy revealed that the incidence of hepatocellular cancer (HCC) was higher in patients treated with DAA (3,4). DAA treatment may also be associated with higher tumor recurrence rate. However, the validity of these data has not been confirmed in different studies (5). In this report, we aimed to present the case of B-cell non-Hodgkin lymphoma (BNHL) in a patient treated with DAA.

Case

A 77-year-old woman has been followed up with chronic hepatitis C since 2009. She was previously treated with pegylated-interferon and ribavirin combination. Although the response was obtained by treatment, relapse was subsequently occurred. In March 2016, laboratory examinations showed a sedimentation rate of 44 mm/h, an alpha fetoprotein level of 9.29 ng/mL, alanine aminotransferase of 62 IU/L, HCV-RNA viral load of 1471602 IU/mL with genotype-1b and the patient was anti-HCV-positive. After relapse, we decided to treat the patient with DAA. The initial complete blood test (November 2016) revealed a hemoglobin level of 135 g/L (normal range: 115-150 g/L), a white blood cell (WBC) count of 6.86x10^9/L (normal range: 3.5-9.5x10^9/L) (neutrophil-69.4%, lymphocyte-23.9%, monocytes-5.82%), and a platelet count of 157x10^9/L (normal range: 125-350x10^9/L).

After splenectomy (December 2017), the values were as follows: WBC: 7060 K/UL (neutrophil-60.8%, lymphocyte-28%, monocytes-9.58%), hemoglobin 11.6 g/L, and platelet 504 K/UL. Before treatment, there was no mass detected by abdominal ultrasonography (USG) (It was done at two times at 2016). She was treated with ombitasvir-paritaprevir-ritonavir and dasabuvir (OPRD) for 12 weeks in November 2016. HCV-RNA became negative after the first month of OPRD treatment. SVR was obtained 12 weeks after the treatment. In June 2017, the patient suffered from fatigue and feeling of fullness and pain in the upper left quadrant. A splenic mass (9x7 cm) was detected USG in the spleen six months after cessation of the treatment (Figure 1).

In June 2018, surgical resection of the splenic mass was done. Histological analysis of the surgical specimen revealed high-grade B-cell NHL. The patient, who is still being followed up in our clinic was cured after three cycles of chemotherapy (R-CHOP chemotherapy protocol) followed by radiotherapy. Written informed consent was obtained from the patient.

Discussion

HCV is a lymphotropic and hepatotropic virus affecting nearly two hundred million people in the world (6,7). We clearly know that BNHL is related with HCV infection. HCV infection has been reported in nearly 13% of patients with BNHL (8). Chronic antigenic stimulation of the immune system by HCV infection may lead to BNHL. A very similar situation applies to Helicobacter Pylori. MALP lymphoma develops as a result of similar pathology in H. Pylori infections (9). T cell-dependent responses are also involved in the pathogenesis of this event. We think that it is very important to decrease the antigenic concentration in the development of malignancy. In addition, we conclude that with the termination of antigenic stimulation, there is a decline in immunity, thus developing lymphoma in an immune organ such as the spleen.

In our case, there was no evidence of malignancy before treatment. However, the development of lymphoma after months of therapy and SVR was interpreted as a lack of immune stimulation. A period of 6-7 months after treatment can be considered as a very short period for the development of lymphoma. However, the fact that there was no mass in the spleen detected by USG before treatment suggests that this condition was related to HCV treatment.

A similar situation applies to HCC. The probability of HCC relapse following DAA in HCV infection treatment is still unclear. The role of the immune system before and after tumor development is very important. HCV-infected liver cells are constantly alerted by the immune system. If infected cells are destroyed, the efficacy of the immune system in the liver is significantly reduced. In some studies, it has been shown that DAA treatment affects natural killer cells (10). In their study, Chu et al. (11) reported that after DAA treatment, a rapid decrease was seen the level of natural killer group 2, member D protein (NKG2D) which is released from natural killer cells. The low level NKG2D was correlated with early HCC emergence in DAA-treatment.

Two different study reported increased HCC after complete response to DAA therapy in patients with HCV (3,4). At this point, the disorder that occurs in the release of these substances may be accelerating the oncogenic process. Virus-induced inflammation may play an important role in chronic liver injury and in the onset of the tumor development in chronic hepatitis (12). However, at the same time, the immune system is necessary to prevent tumor formation (13). Again, as long as there are cells that are infected with HCV, the immune system is also actively working to destroy these cells. If HCV clearance occurs, the immunosuppressive effect of the system (both for virus-infected cells and tumor cells) is degraded. Immune regression also accelerates tumor development.

Lastly, we think that the risk of cancer in patients receiving DAA suggests that these patients should be monitored closely after therapy is completed.

Ethics

Informed Consent: Written informed consent was obtained from the patient.

Peer-review: Externally and internally peer-reviewed.
Authorship Contributions

Conflict of interest: The authors declare that they have no conflict of interest.

Financial Disclosure: The authors declared that this study received no financial support.
