Interpreting a Radical Prostatectomy Report

Radikal Prostatektomi Raporunun Yorumlanması

Abstract

Worldwide, clinically detected prostate cancer is the second most common malignancy, with an estimated 1.1 million new cases in 2012. Standard active treatments for prostate cancer include radiotherapy and/or radical prostatectomy (RP) (for clinically localized prostate cancer). Also active surveillance is a management strategy to avoid or delay the potential harms caused by radical treatments. At this point, a pathology report plays a major role. Appropriate handling and systematic examination of a RP specimen is essential for the identification of tumor characteristics such as grade, volume, pathological stage, and surgical margin status. Although some minor differences in macroscopic evaluation may be seen among authors, it is essential to paint and sample the entire prostatectomy specimen. Most prostate tumors are heterogeneous and multifocal compared to tumors of other organs. This makes macroscopic assessment of prostatectomy specimen challenging and sampling of a representative material from the main tumor focus difficult. Also determining tumor burden and to interpret all surgical margins total sampling of the material is essential.

Introduction

Interpreting a Radical Prostatectomy Report

Clinically diagnosed prostate cancer was the second most common malignancy in the world in 2012 (1). Radiotherapy and, for clinically localized form, radical prostatectomy (RP) are standard active treatments for prostate cancer. In addition, active surveillance is a management strategy in appropriate patients to prevent or delay the potential harm caused by radical treatments.

At this point, pathology report plays a major role. Appropriate handling and systematic examination of a RP specimen is essential for the identification of tumor characteristics such as grade, volume, pathological stage, and surgical margin status. Although some minor differences in macroscopic evaluation may be seen among authors, it is essential to paint and sample the entire prostatectomy specimen. Most prostate tumors are heterogeneous and multifocal compared to tumors of other organs. This complicates the macroscopic evaluation of the tumor.

Determining tumor burden and interpreting all surgical margins total sampling of the material is essential.

The eighth edition of the American Joint Committee on Cancer (AJCC) cancer staging manual (8E AJCC) includes some changes in staging prostate cancer (2). To briefly summarize, there is no pT1 category for RP specimens anymore. Several retrospective...
outcome data analyses subdividing pT2 disease into three categories as pT2a, pT2b, and pT2c have no prognostic value. No data exist to allow correlation of pT2 stage subgrouping with survival in localized prostate cancer due to the indolent and prolonged clinical course of the disease. In the 8E AJCC TNM staging manual, pT3 disease is subdivided into two categories as pT3a and pT3b, evaluating the presence of extraprostatic extension (EPE) and the presence of seminal vesical invasion with or without EPE. In the 8E AJCC, microscopic bladder neck invasion is considered as pT3a, similar to the old version (2).

Periseminal vesicle soft tissue invasion, staged as pT3a (EPE), should be distinguished from seminal vesicle invasion (pT3b) that keeps the tumor cells in the muscular wall of the seminal vesicle. In the revised form, there is no change for staging LN metastasis in prostate cancer. Tumor that is fixed or invades adjacent structures other than seminal vesicles, such as rectum, bladder, levator muscles or pelvic wall, is categorized as pT4 (Table 1) (2,3).

The International Society of Urological Pathology (ISUP) consensus conference held in March 2009 in Boston made recommendations for standardization of pathology reporting of RP samples. The results of the meeting are presented in five subsequent workgroup reports (4).

In fact, this is not a pure pathology text to elaborate staging. Pathology reports play a major role in the implementation of new treatment modalities. As known, pathology is a rapidly changing and developing science, and there are many parameters in a prostatectomy report which must be interpreted by urologists.

In order to understand the messages given in a pathology report, the urologist and the pathologist should speak the same language. The goal of this review is to provide information for urologists to take all messages given by the pathologist in a RP report.

EPE (focally or extensively), intraprostatic incision (IPI), surgical margin positivity (PSM) in the presence of IPI, and PSM in the presence of EPE are the parameters which are commonly used in RP reports besides the identification of tumor characteristics such as grade, volume, pathological stage, and surgical margin status.

Here, we briefly summarize these parameters;

**Extraprostatic extension:** TNM staging system for prostate cancer defines pT3a as extension of tumor into periprostatic soft tissue. The terms of capsular penetration and capsular invasion are not recommended to be used anymore, because the prostate has not got a true histological capsule. Therefore, EP is the preferred terminology (5,6). In fact, there is limited data to assess interobserver agreement between pathologists in the evaluation of EPE. Two separate studies on this subject have shown a significant variability between experienced pathologists and non-specialists (7,8).

The most easily recognizable sign EPE is determining tumor cells in periprostatic fat. In fact, it varies according to different regions of the prostate; EPE is most commonly identified in the posterolateral part of the gland, because the tendency of perineural spread of the prostate tumor is considered as the basic extraprostatic spreading mechanism (9). A bulging tumor nodule beyond the normal contour of the gland can also be recognized as EPE (9).

Tumors detected in apex/distal border sections are not considered extraprostatic spread because benign glands can often be found within the striated muscle, as a result of which the malignant glands in the striated muscle cannot be considered an extraprostatic spread (7,8).

The extent of EPE should be mentioned in a pathology report, because radial distance of EPE is the only independent predictor of PSA failure recurrence in multivariate analysis (10). Therefore, assessing the EPE, the terms “focally” and “extensively” are recommended to be used in the reports (1,11,12). Focally means, a few neoplastic glands just outside the prostate or extraprostatic tumor occupying less than one high-power field in no more than two sections, and extensively means more than focal (11,12).

Of course PSM should be indicated separately in the EPE focus (Figure 1.2).

Intraprostatic Insicion means that the surgeon was unable to remove the entire prostate and some of the prostate tissue remained in the patient. IPI has a significant negative impact on patient outcome following RP (13,14,15,16,17,18). The urologist should know that there may be no biochemical remission in the presence of IPI. PSM may occur as a consequence of IPI so the pathologists must specify if there is a tumor on focus of IPI (Figure 3,4), because it is associated with decreased biochemical recurrence-free survival (19,20).
Also it is recommended determine Gleason score of tumor at the PSM focus (19).

Bladder neck invasion was designated as pT4 disease in the 2002 AJCC TNM staging system, whereas, microscopic bladder neck invasion was categorized as pT3a cancer in the 2009 TNM (21).

The results of ISUP consensus meeting on microscopic bladder neck invasion revealed that tumor involving the bladder neck, specifically defined as neoplastic cells within thick smooth muscle bundles, should be reported as pT3a. For categorization as pT4, gross invasion of the bladder neck is required. In the presence of malignant glands intermixed with benign glands in the bladder neck, this should be considered equivalent to the IPI; if tumor is present at the inked resection margin at the bladder neck, this should be stated in the pathology report (10,22,23).

In fact, there are controversies as to whether microscopic bladder neck invasion is an independent histological prognostic parameter.

In multivariate models, bladder neck invasion was found not to be an independent predictor of PSA failure recurrence after RP, and prognosis was dependent on other pathological features (24). The importance of microscopic bladder neck invasion has not been clarified yet. Nowadays there are new studies going on for this topic.

**Conclusion**

As mentioned before, this is not a pure pathology text to elaborate staging. Therefore, it has been prepared without detailing the pathology to draw attention of the clinician to some newly defined parameters. Thus, pathologists may not find more details in this text.

When evaluating a pathology report, urologists should be able to interpret the details given in the report without looking for the term “capsule invasion” anymore.
