
Ürolojik Operasyonlar Sonrası Ortaya Çıkan Torasik Komplikasyonların Değerlendirilmesi: Tek-merkez Deneyimi

**What's known on the subject? and What does the study add?**

Thoracic complications are a major complication of urological surgery. Complications are an inevitable part of urological surgery due to the increasing number of cases and complexity in recent years. There are some data on thoracic complications after urological laparoscopic surgery in the literature, while data on a thorough analysis of the thoracic complications of urological surgery is limited. In this study, we present the thoracic complications of the cases operated in our clinic and the treatment methods performed by the thoracic surgery clinic.

We concluded that early diagnosis of thoracic complications and coordinated work with thoracic surgery are fundamental.

**Abstract**

Objective: To present cases of thoracic complications that developed after urologic interventions and were treated in collaboration with thoracic surgery.

Materials and Methods: Patients who were operated in the urology clinic of our hospital between January 2014 and December 2017 and required thoracic surgery consultation were retrospectively reviewed. Forty-two patients with pneumothorax, pleural effusion, hydropneumothorax and diaphragm injury were included in the study. Six patients, who had preoperative diaphragm invasion and underwent preoperative diaphragm incision, were excluded.

Results: Tube thoracostomy (TT) was applied in only 5 patients who developed pneumothorax. Three patients with isolated pleural effusion were treated with TT and 3 with thoracentesis. All patients who developed hydropneumothorax were found to have undergone nephrectomy (3 left, 1 right). All patients with iatrogenic diaphragmatic injury were diagnosed perioperatively and all of these patients were nephrectomized (5 right, 1 left). All the patients underwent primary diaphragm repair and 5 patients underwent TT. The mean duration of tube drainage was 5.5±2.1 (2-13) days. The mean length of hospital stay in patients who underwent percutaneous nephrolithotomy, nephroureterectomy, nephrectomy and prostatectomy with thoracic complications was 4.12±1.08, 8.26±2.87, 4.04±1.23 and 4.17±0.72 days, respectively. There was no significant difference in mean duration of hospital stay between patients with and without thoracic complications (p=0.729).

Conclusion: Thoracic complications may develop after urological interventions. In particular, evaluation of chest pain in patients with right-sided percutaneous nephrolithotomy and nephrectomy by chest X-ray is important for early diagnosis.

saptanan 42 hasta dahil edildi. Operasyon öncesi diyafragma invazyonu saptanan ve peroperatif diyafragma insizyonu yapılan hasta çalışma olmadan çıkarıldı.

Bulgular: Pnömotoraks gelişen hastaların sadece 5’ine tüp torakostomi (TT) uygulandı. İzole pleval effüzyon izlenen hastaların 3’ü TT, 3’ü ise torsaente ile tedavi edildi. Hidropnömotoraks gelişen hastaların tamamında nefrektomi (3 sol, 1 sağ) uygulandığı görüldü. İyatrojenik diyafragma yaralanması gelişen hastaların tamamına peroperatif dönemde tanı kondu ve hastaların tamamı nefrektomi (5 sağ, 1 sol) hastası idi. Hastaların tamamında diyafragmanın primer onarımı yapıldı, 5 hastaya TT uygulandı. Hastaların ortalama dren kalış süresi 5,5±2,1 (2-13) gündü. Toraks komplikasyonu gelişen hastaların peroperatif dönemde nefrolitotomi, nefroüreterektomi, nefrektomi ve prostatektomi operasyonu geçiren hastaların ortalaması ortalama hospitalizasyon süreleri, sırasıyla, 4.12±1.08, 8.26±2.87, 4.04±1.23 ve 4.17±0.72 gündü. Toraks komplikasyonu gelişen ve gelişmeyen hastaların ortalama hospitalizasyon süreleri arasında anlamlı bir farklılık yoktu (p=0.729).

Sonuç: Ürolojik girişim sonrası torsalik komplikasyonlar gelişebilir. Özellikle sağ taraflı perkutan nefrolitotomi ve nefrektomi sonrası göğüs ağrısı tarifleyen hastaların akciğer grafisi ile değerlendirildiği arken tanı için önemli bir öneme sahiptir.

Introduction

Each surgical procedure has a certain risk of complications. Urological surgery, whether open or endoscopic, may be associated with visceral, vascular and thoracic complications. Along with technical and technological advances, in recent years, urologic surgery has evolved from open to endourological methods. With the increase in the number and complexity of cases, the complications caused by surgery have become inevitable. So far, there has been no overrepresentation in the literature on the thoracic complications of urological surgeries, with a focus on vascular and visceral complications (1,2,3). Moreover, most of these complications are related to laparoscopic surgery. A multi-center study focused on pleural damage in laparoscopic renal surgery (4). In another large study, thoracic complications encountered during laparoscopic urology were discussed under the headings medical pulmonary complications, surgical thoracic complications, and subclinical and incidentally detected gas collections in the thorax (5).

Urological surgery itself can often be the cause of thoracic complications, and the position given to the patient may also cause complications. A case of upper lobe atelectasis due to lateral decubitus position during radical nephrectomy under general anesthesia that was successfully treated with saline lavage and bronchoscopic suction has been reported (6). Therefore, urologic surgery-related thoracic complications should be comprehensively considered in conjunction with their etiology and course and treatment methods. In this retrospective analysis, we evaluated thoracic complications occurred in patients, who were operated in our clinic, their etiology and the methods of management performed by thoracic surgery.

Materials and Methods

Patients and Selection Criteria

A total of 48 patients who were operated in the urology clinic and required perioperative and/or postoperative thoracic surgery consultation between January 2014 and December 2017 were the material of this study. Patients, who had pneumothorax, pleural effusion, hydropneumothorax or diaphragm injury due to surgical intervention or anesthesia technique and were managed by the thorax surgery clinic (n=42), were included in the study. Patients who had preoperative diaphragm invasion due to local tumor spread (n=2) and underwent perioperative diaphragm incision (n=4) were excluded. The data of the patients were obtained from the hospital registry system and patient files in the urology and thoracic surgery clinics. The study was carried out in accordance with the principles of the Declaration of Helsinki and all patients included in the study gave consent for research use of their data, provided their identities would be kept confidential.

Management Techniques of Patients

Appropriate follow-up, oxygen inhalation therapy, thoracentesis or tube thoracostomy (TT) treatments were applied by the department of thorax surgery.

Data Collection and Analysis

Demographic data of the patients, urological procedures, thoracic complications and treatment methods applied by the thoracic surgeons were analyzed. The characteristics of the patients with and without thoracic complications were compared by using the unpaired t-test. P values less than 0.05 were considered statistically significant.

Results

Of the 42 patients included in the study, 27 (64.3%) were male and 15 (35.7%) were female. The mean age was 52.81±16.15 (23-85) years. Pneumothorax was the most common thoracic complication (61.9%) followed by pleural effusion, diaphragmatic injury, and hydropneumothorax (17.2%, 17.2% and 9.5%, respectively). It was observed that pneumothorax most often developed after percutaneous nephrolithotomy (PCNL) (n=15).
The other patients who developed pneumothorax were those who have undergone nephrectomy (n=8), prostatectomy (n=2) and laparoscopic nephroureterectomy (n=1). The diagnosis of pneumothorax was most frequently made in the early postoperative period (n=16). In addition, it was made on the postoperative 1st day in 5 patients and postoperative day 4 in 1 patient.

Thoracic complications observed according to urological interventions are given in Table 1.

Only 5 patients required TT. The mean duration of drainage was 4.6±2.1 (2-8) days. Other patients were followed up with oxygen inhalation. Isolated pleural effusion was seen in 6 patients. Three of these patients underwent PCNL and 3 underwent nephrectomy. Three of these patients underwent TT and 3 had thoracentesis. The mean drainage time was 6.66±5.51 (3-13) days in these patients. The implementation of a TT for hemothorax developing in the left thorax after PCNL is shown in Figure 1.

All patients who developed hydropneumothorax had undergone nephrectomy. Three patients underwent TT and the mean drainage time was 5.66±2.89 (4-9) days. Patients with iatrogenic diaphragmatic injury were diagnosed in the perioperative period and all of them had undergone nephrectomy. In these patients, diaphragm was repaired primarily and TT was applied in 5 patients. The mean duration of drainage was 5.2±2.28 (2-8) days in these patients. The management of thoracic complications and the duration of thoracostomy tube drainage are summarized in Table 2.

PCNL was performed in 706 patients, nephroureterectomy in 95, nephrectomy in 819 and prostatectomy in 1565 patients during the study period. The rate of thoracic complications for PCNL, nephroureterectomy, nephrectomy and prostatectomy operations was 2.54%, 1.05%, 2.56% and 0.13%, respectively.

The mean length of hospital stay in patients who underwent PCNL, nephroureterectomy, nephrectomy and prostatectomy with thoracic complications was 4.12±1.08, 8.26±2.87, 4.04±1.23 and 4.17±0.72 days, respectively. In the same period, the mean length of hospital stay in patients who underwent PCNL, nephroureterectomy, nephrectomy and prostatectomy without thoracic complications was 3.28±0.68, 7.11±1.79, 3.04±0.62 and 4.13±0.69 days, respectively. There was no significant difference in mean length of hospital stay between the two groups (p=0.729).

Discussion

Different thoracic complications may be encountered after both open and endo-urological operations. This article, in which we presented the thoracic complications and the treatment methods applied for them, revealed that the most common thoracic complication was pneumothorax and nephrectomy was the most common operation following thoracic complications. Follow-up was the most common management method for thoracic complications utilized by the thoracic surgery. TT was the second most commonly used intervention after follow-up.

The classification system, which was first described in 1992 by Clavien et al. (7) to convey a recognition and standardization of surgical complications, has been modified in 2004 (8). This system is widely accepted for the classification of surgical complications and classifies them in a spectrum ranging from grade I to V. Pulmonary complications are included in all subgroups and those constitute important components of the classification. For instance, atelectasis requiring physiotherapy as grade I; pneumonia treated with antibiotics as grade II; bronchopleural fistulas requiring surgical closure after thoracic surgery as grade IIIb; respiratory failure requiring intubation as grade IVa, and renal failure in addition to grade IVa is classified as grade IVb complication.

Pneumothorax may be due to several reasons after abdominal surgery. It can be seen as a complication of anesthesia as well as surgical procedure. Laparoscopic and open surgery may induce pneumothorax with different mechanisms. Congenital diaphragmatic defects may allow peritoneal carbon dioxide (CO₂) to pass into the pleural space in laparoscopic surgery (9,10). CO₂ may cause pneumothorax by dissecting the pulmonary hilum after entering the mediastinum or through a rupture in the mediastinal pleura and entering the pleural cavity (10). In addition, apical pneumothorax may occur due to rupture of apical blebs due to barotrauma caused by positive pressure in mechanical ventilation (9). Needle aspiration of the pleura can help distinguish whether the pneumothorax is due to endotracheal anesthesia or the CO₂ accumulation into the tissue. In our series, pneumothorax most commonly occurred in patients undergoing PCNL. All these patients had upper calyceal stones and had undergone high level-needle access (10-11 or 11-12 rib interspace). During this time, maximum expiratory-inspiration maneuver was performed in coordination with anesthesia. This maneuver and high level-needle access are likely to cause this complication. Asymptomatic CO₂ pneumothorax typically spontaneously resolves with conservative management. It regressed with O₂ support in the majority of our patients; only 5 patients required TT. They were also treated with short-term tube drainage. Two patients who underwent prostatectomy had pneumothorax. These cases were performed by open surgery. We consider that barotrauma was the possible etiologic factor in these patients. In order to prevent abdominal gas collections, it is important to maximize abdominal muscle relaxation and prevent coughing and straining, especially during laparoscopy (11). If an intraoperative pleural or diaphragmatic damage occurs, the anaesthesiologist should be warned immediately. Ventilator parameters should be carefully controlled and allowed to complete the surgical procedure and repair any damage.

The risk of a pleural or lung injury during PCNL operation is about 10% when the puncture is above the 12th rib. If pleural effusion occurs, a thorax tube is required. The choice of lower caliceal access and the combination with flexible nephroscope or extracorporeal shock wave lithotripsy may prevent this complication (12,13). Pleural effusion occurred in our patients who underwent PCNL and nephrectomy. These patients were treated with thoracentesis or TT. The rates of thoracic complications after PCNL have been reported to be between 0% and 11.6% in different studies (14,15,16). In our study, it was found to be 2.54% in accordance with the literature.

Diaphragmatic damage is a rare but well-diagnosed complication of renal surgery. Particularly in upper pole tumors, tear of the diaphragm during dissection due to tumor invasion or injury damage due to the cautery may occur. In this complication, primary repair of the damage site is the most appropriate approach. In open surgery, primary suturing and underwater drainage can be performed, and in laparoscopic surgery, repair of the damaged area by intracorporeal suturing can be performed. A diaphragmatic injury that occurred during laparoscopic nephrectomy was treated with intracorporeal suturing and chest tube, and the CO₂ pneumothorax was rapidly resorbed (9). Gonzalez et al. (17) described an alternative method for repairing diaphragmatic damage occurring during
hand-assisted laparoscopic nephrectomy. The authors patched a polypropylene and polyglactin dual mesh with a laparoscopic stapler on the tear of diaphragm and then inserted a chest tube. The patient recovered without sequelae. In another case, gelatin matrix was used as an alternative to suturing for repairing a diaphragmatic tear. Gelatin thrombin matrix was applied to the tear area through a trocar and the defect was successfully repaired (18). This method can be successfully applied in selected small diaphragmatic defects. The rate of thoracic complications after open renal surgery has been reported to be between 3% and 10% in different studies (19,20). In our study, it was found to be between 1% and 2.5%, less than in the literature. The probable cause of this low rate was our advanced experience in renal surgery and the prevention of high gas pressure by providing coordination with anesthesia during laparoscopic surgery. Recently, in a prospective study, factors that predicted pleural injury during PCNL were evaluated. Three hundred thirty-two patients were divided into two groups according to development of pleural injury and the higher risk of pleural injury was found to be associated only with low body mass index and younger age in multivariate analysis (21).

**Study Limitations**

Although our study is one of the rare studies presenting thoracic complications of urological surgeries from a single-center, it is not without limitations. Firstly, limited number of cases and its retrospective nature are the main limitations. Second, direct radiography with lower sensitivity was used in the diagnosis of pleural complications instead of computed tomography.

**Conclusion**

In conclusion, it should be kept in mind that thoracic complications may occur during urological surgeries. It is essential to diagnose complications (perioperative if possible) immediately and to work in coordination with anesthesiologists and to consult with thoracic surgeons.
