CASE REPORT

A rare cause of acute abdomen; paratubal cyst torsion

Introduction

Paratubal cysts constitute 10-20% of all adnexial masses and they exist in the broad cord between the ovary and tube. They arise from mesonephric, mesotelial or mesonephric remnants. Even if paratubal cysts have been reported in all female age groups, they are seen mostly in between 20 and 40-year-old women. These cysts have thin walls. Preoperative differential diagnose is very difficult due to the closeness to the ovary. Paratubal cysts are usually small and asymptomatic. However, bigger lesions can reach a size of 20 cm or more and become symptomatic with complications such as torsion, hemorrhage, perforation and neoplasm (1). Most of these cysts are benign; on the other hand, borderline tumors and carcinomas have been reported as well. Smaller lesions can be followed. Bigger lesions, symptomatic lesions and sonographic uncertain findings (septations, papillations, liquid and solid components) are usually investigated surgically. Classic treatment is the enucleation of the cyst from the mesosalpynx without damaging the ovaries and fallopian tubes (2). However, salpyngooopherectomy can rarely be needed in complicated cases (3,4). In this article, we present the management of a patient who had an abnormally large paratubal cyst.

Presentation of Case

Our patient was a 43-year-old female, having 3 gravidities and 3 parities. The main complaint of our patient was abdominal pain which had been lasting for two months. During physical examination, the abdomen was distended and there were general palpational sensitivities.

In the abdominal tomography, a 28x22 cm mass was detected and evaluated as mesenteric cyst, which reached from the epigastric area to the pelvis in abdominal midline superior, to abdominal wall in anterior, to prevertebral area in posterior, and to the intestines in lateral areas. Free fluid was seen together with the cyst in inferior. The physical examination and ultrasonographic scan were performed as a result of the consultation of obstetrics and gynecology and no gynecological pathology was evaluated. The patient was evaluated as anemic...
in the tests (hemoglobin: 7.74 g/dL, hematocrit: 24.63%). All the other tests including tumor markers were seen in normal limits.

During explorative laparotomy, a purple, about 25-30 cm mass was seen as soon as the abdomen was entered. The mass was seen as left ovarian originated and tortured. It was detorted. Then, it was excised with the ovary by fixing its root. Free fluid was seen inside the abdomen and a sample was taken for pathological study. Then, it was aspirated. Inside of the abdomen was washed abundantly with saline. The right ovary and uterus were evaluated as normal. Then a Jacksonpratt drainage was placed in the Douglas cavity. The operation was finished by closing the layers anatomically (Figures 1, 2).

The patient was discharged after pulling the drainage out on the postoperative 5th day. In the pathological study, serohemorrhagic fluid discharge from the cystectomy material was seen. The wall of the cyst was seen as hemorrhagic and brown purple colored. Macrophages full of hemosiderin were seen on the wall of the cyst. When the abdominal fluid was studied pathologically, it was seen as malignancy-negative.

**Discussion**

Paratubal cyst is a vesicle which is full of liquid and unilaterally growing on the broad ligament between the uterus and ovary. The origin of these tumors can be referred to the ovaries because tubes cannot usually be seen in ultrasonographic examination.

Characteristic ultrasonographic findings such as non-stromal, unilateral cystic mass can help the differential diagnosis of paratubal cyst. Paratubal cysts are assumed that they are originated from the remnants of paramesonephric (mullerian) and mesonephric (wolffian) ducts which exist during urogenital embryologic development.

Paratubal cysts constitute 10% of whole adnexial masses (5). They are not rare, but they are found incidentally because they are usually asymptomatic. Therefore, the real incidence of them is actually unknown. When paratubal cysts are symptomatic, they often appear with unilateral pelvic pain. Symptoms start to appear when the cyst grows extremely, bleeds, and becomes tortured or ruptured. In our case, the cyst was extremely growing with tortion and hemorrhage.

Paratubal cysts are usually bound to mesosalpynx with a peduncle and tortion can occur around this (6,7). The incidence of paratubal cyst is uncertain but it must be suspected in the patients with acute or intermittent pelvic pain. In most cases, the diagnosis of tortion can be made with only surgical exploration. Malignant neoplasms can sometimes develop in paratubal cysts (8).

The size of paratubal cysts can change between 2 and 20 cm but most of the cases are between 6 and 10 cm (9). Bigger paratubal cysts were reported in the literature (10,11). The size of the cyst was measured as 30 cm and weighted at 4.5 kg in our case.

Treatment options for paratubal cysts can be selected according to the patient’s age, parity, existing gynecologic pathologies and neoplastic degeneration. There is no need to intervene or constantly observe for paratubal cysts which have a radius of <10 cm and are seen simple in ultrasound. Surgical treatment of paratubal cyst is simple excision. Giant paratubal cysts are extraordinary masses and they must be treated with laparotomy. Laparoscopic approach is also reliable, but the size of the cyst is a limiting factor.

Conclusion

Consequently, if there is not any ultrasonographic malignancy criteria in giant cystic masses, paratubal cyst must be considered in differential diagnosis. Cyst excision protecting the ovary is enough in cases without any complications. Salpyngooopherectomy must be performed as well in the tortion cases with circulation disorder and suspicion of malignancy.
