Dear Editor,

Coronavirus Disease-2019 (COVID-19), as an outbreak, is associated with high morbidity and mortality. Since it affects the elderly more than other age groups, intensive care requirement and the risk of cardiovascular diseases and stroke become important due to the wide usage of antithrombotic medication. As a result of potential drug-drug interactions, these high-risk medications may cause gastrointestinal bleeding. We believe that identifying drug-drug interactions between COVID-19 and antithrombotic medications, which are commonly used in patients in the intensive care unit who suffer from cardiovascular diseases or stroke, is beneficial to ensure appropriate and safe treatment.

Hydroxychloroquine, a first-line treatment option for COVID-19, has a few drug interactions with antithrombetics. Although hydroxychloroquine does not have any drug-drug interaction with other antithrombotics (such as heparin, enoxaparin, aspirin, clopidogrel, and warfarin), it can increase the blood levels of apixaban (low risk), dabigatran (moderate risk), edoxaban (moderate risk), and rivaroxaban (low risk). Lopinavir/ritonavir (LPV/r) combination and strong inhibitors of cytochrome P450-3A4 and P-glycoprotein may enhance the blood levels of apixaban (high risk), dabigatran (moderate risk), dipyridamole (moderate risk), and warfarin (moderate risk). It is recommended to adjust the dose of LPV/r to 2.5 mg twice daily. Concurrent use of oseltamivir and warfarin (low risk) can lead to increased serum concentration of warfarin; however, this interaction does not require any intervention except monitoring the international normalized ratio. Additionally, clopidogrel (moderate risk) may decrease the serum concentrations of active metabolites of oseltamivir.

In some countries, the use of azithromycin in combination with hydroxychloroquine is the most common approach among treatment options of COVID-19. In case of concomitant use of azithromycin during venous thromboembolism treatment with edoxaban, the serum concentration of edoxaban may significantly increase, which leads to the risk of exceeding its maximum daily dose (30 mg). The use of azithromycin with apixaban (minor risk), rivaroxaban (low risk), dabigatran (moderate risk), or warfarin (moderate risk) may enhance the serum concentration of these antithrombotic drugs.

In terms of interaction with antithrombetics, because of limited data available at the moment, favipiravir seems to be the safest option among other medications used in COVID-19 treatment. The interaction of favipiravir with antithrombotic drugs has not been reported.
During COVID-19 treatment, concomitant use of high-risk medications such as antithrombotics should be assessed carefully for drug-drug interactions to avoid any negative outcomes in the treatment process.
