A Decline in Aminotransferase Activity Due to Lifestyle Modification in Children with NAFLD

Pawel Malecki, Anna Mania, Katarzyna Mazur-Melewska, Wojciech Sluzewski, Magdalena Figlerowicz

Poznan University of Medical Sciences, Department of Infectious Diseases and Child Neurology, Poznan, Poland

We are terribly sorry to announce that Professor Wojciech Sluzewski passed away on the date of 19 September 2020. We thank him for his contributions.

ABSTRACT

Aim: As obesity rates in children and adolescents increase, non-alcoholic fatty liver disease (NAFLD) has become the most common liver disease affecting this organ. This study aimed to evaluate the effectiveness of lifestyle modifications as a method of improving liver function indexes in children with NAFLD.

Materials and Methods: The study group consisted of 49 patients with NAFLD (35 boys and 14 girls), age range 3-16 years (mean 10.51±3.18 years). Anthropometric measurements were taken and laboratory tests were performed. Features of steatosis of the liver were evaluated by ultrasound. The mean follow-up period was 2.45±1.45 years. Aspartate aminotransferase (AST) to [Platelet (PLT) Ratio and Pediatric NAFLD Fibrosis Score (PNFS)] were calculated. The Mediterranean diet and physical exercises were recommended. End-point parameters were a decrease in the aminotransferase level and body weight.

Results: In the study group, 35 children (71.43%) were obese, and 7 (14.29%) were overweight. In 22/49 cases (44.9%) body mass index (BMI) loss was achieved, in the other patients, BMI gain was noted. Abnormal alanine aminotransferase (ALT) levels were observed in 25/49 children. In the group of children with initial increased ALT levels, significant reduction of ALT, AST and gamma-glutamyltransferase (GGT) levels were found with regard to baseline values. There was also a significant decline in mean AST to PLT Ratio index (APRI) level and PLT count. Moreover, a decrease in ALT level was negatively related to PNFS, APRI and GGT.

Conclusion: Lifestyle modification leads to a significant decrease in aminotransferase levels, even in children who fail to achieve BMI reduction.

Keywords: Fatty liver, obesity, children, aminotransferases

Introduction

Non-alcoholic fatty liver disease (NAFLD) is currently the most common chronic liver illness in children (1). This term describes a broad spectrum of liver disorders, ranging from simple steatosis to non-alcoholic steatohepatitis. Its estimated prevalence ranges from 3% to 12% in the general pediatric population and up to 70% in obese children (2). Suspicion of liver steatosis is usually based on imaging studies - a characteristic, hyperechogenic picture of the liver in abdominal ultrasound is the most commonly used mode of assessment. Diagnosis is established by excluding other causes of liver damage (drug poisoning, viral hepatitis, autoimmune liver disease, inborn errors of metabolism, alcoholism) (3,4).

With regard to the increase in the incidence of NAFLD, also in the pediatric population, and the possible consequences caused by its complications, the search for treatment methods has become the subject of many scientific studies.
According to the guidelines created recently by two medical societies, namely the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition and the American Association for the Study of Liver Diseases (AASLD), lifestyle modification remains the primary method of treatment. Currently, there are no clear guidelines which present precise recommendations on lifestyle changes, such as diet type or specific weight loss. Recommendations are extrapolated from studies on the adult population. In everyday clinical practice, the first step in both the diagnosis and assessment of disease progression is to determine aminotransferases and abdominal ultrasound.

Liver fibrosis is an independent factor increasing the risk of liver-related complications and mortality (5). Liver biopsy remains a golden although imperfect standard when steatohepatitis or liver fibrosis is suspected. Furthermore, the procedure should be performed in the case of uncertain diagnosis, possible overlap syndromes or additional risk factors such as type 2 diabetes. Nevertheless, since liver biopsy is an invasive procedure with its own bias, initial assessment of fibrosis and inflammation of the liver tissue is usually performed using non-invasive tools such as serum markers or panels of markers (6). Non-invasive evaluation of fibrosis has been the subject of research of scientists for several years. Panels based on basic laboratory tests and anthropometric measurements [e.g. Aspartate aminotransferase (AST) to [Platelet (PLT) Ratio index (APRI)], Pediatric NAFLD Fibrosis score (PNFS)] are used as well as and more extensive ones, requiring more specific tests (e.g. cytokeratin 18, enhanced liver fibrosis). Serum markers enable the repetitive assessment and therefore, are used as a tool for the monitoring of the treatment (7,8).

The aim of this study was to evaluate aminotransferase level and liver damage indexes with regard to the decline in body weight as a result of lifestyle modifications in children with NAFLD.

**Materials and Methods**

The group in our prospective, consecutive study consisted of 35 boys and 14 girls, with a diagnosis of NAFLD, age range 3-16 years (mean 10.51±3.18 years), who visited the Hepatology Outpatient Clinic at the Department of Infectious Diseases and Child Neurology. The sample size was determined using “Sample Size Calculator” (https://clincalc.com/stats/samplesize.aspx). The result should not exceed 1.

Complete blood count, alanine aminotransferase (ALT), AST, gamma-glutamyltransferase (GGT) and serum lipids were assessed on standard laboratory analyzers. Normal upper values for liver enzymes were as follows: ALT <12 yo: boys <40 IU/L, girls <35 IU/L; >12 yo: boys <26 IU/L, girls <22 IU/L, AST <12 yo: <45 IU/L, >12 yo: boys <29 IU/L, girls <25 IU/L, GGT 4-24 IU/L.

The Homeostatic Model Assessment of Insulin Resistance (HOMA-IR) was calculated according to the following formula:

\[
\text{HOMA-IR} = \left( \frac{\text{insulin (mU/mL)} \times \text{glucose (mmol/L)}}{22.5} \right)
\]

The result should not exceed 1.

**Non-invasive Hepatic Fibrosis Scores**

APRI and PNFS were calculated based on established formulas (8,12).
APRI = AST/ULN (upper limit of normal)/PLTs (G/L)*100. APRI >1.0 has a sensitivity of 76% and specificity of 72% for predicting cirrhosis. APRI >0.7 has a sensitivity of 77% and specificity of 72% for predicting significant hepatic fibrosis. The lower the APRI score (<0.5), the greater the negative predictive value and the ability to rule in cirrhosis.

PNFS (probability distribution) = \( \frac{e^{z}}{1+e^{z}} \) *100; z=[1.1+(0.34*√ALT) + (0.002*ALP) - [1.1*log(PLT G/L)]-(0.02*GGT)

**Intervention and Control Visits**

Before enrollment to the study, ALT and AST levels were evaluated at least 3 times with an interval of 3 to 6 months. Enrolled patients were recommended to modify their lifestyle: moderate aerobic physical exercise (at least 60 minutes 5 times a week), for example, brisk walking, cycling, swimming and additionally the Mediterranean diet - 5 portions of vegetables and fruits per day, olive oil, higher fish intake (at least 2-3 portions per week), cereals or grains and dairy products (milk, yoghurt) for breakfast, nuts (at least 1 portion per week), pasta or rice almost daily, and also a reduction in red meat, simple sugars and saturated fat. It was recommended to avoid sugar and sugar-containing beverages. It was also recommended to use computers/other screen equipment or watch TV for less than 2 hours a day. Weight reduction was not recommended in children with BMI within reference values. However, lifestyle modification was introduced in this group of children to reduce ultrasound abnormalities in the liver. Compliance to all parts of lifestyle intervention was carefully evaluated during every visit based on medical history, interviews with the children and their caregivers as well as the analysis of the weekly menu diary. All children were followed every three months during the first year of the follow-up and every 6 months afterwards during outpatient visits. The result as a note “adheres to/does not comply with lifestyle modification principles” was marked. The restriction modifications were semi-quantified: red meat less than twice a week, elimination of fast-food and sweets, drinking water instead of sweet drinks. The physical level was assessed according to the principles described above. The mean follow-up period was 2.45±1.45 years.

Statistical Analysis

Statistical analysis was made with STATISTICA (version 13, TIBCO Software Inc., Palo Alto, USA). Data were presented as the mean ± SD. Mann-Whitney U or Student t-tests were used to compare continuous variables, where appropriate. Pearson chi-square test was applied to categorical variables. Kruskal-Wallis test was used for testing whether samples originate from the same distribution. Wilcoxon-Signed rank test was used to evaluate dependent parameters. We used Fisher’s Exact test in the analysis of contingency tables. Correlations were performed using the Spearman rank correlation test. P<0.05 was considered statistically significant.

The study design was approved by the Bioethics Committee of the Poznan University of Medical Sciences (no: 1074/17 of 9th November 2017). Informed consent was obtained from each patient included in the study. The study protocol follows the ethical guidelines of the 1975 Declaration of Helsinki as reflected in a priori approval by the institution’s human research committee.

Results

Boys comprised the majority of the study group (35/49, 71.43%). In the whole study group, 35 children (71.43%) were obese, 7 (14.29%) were overweight, and 7 (14.29%) had normal weight. All patients were advised to modify their lifestyle according to described suggestions. In 22/49 cases (44.9%) BMI reduction was achieved (at least 10% from the baseline), in the remaining ones (27/49, 55.1%) BMI increased compared to initial values. In the study group, patients who followed lifestyle modification advice were compared to the group who did not follow the regimen. The latter group was considered as a comparative group. Among patients with a decrease in BMI, 100% complied with the recommendations for lifestyle changes. In the group with an increase in BMI, all of these patients were described as "does not comply with the lifestyle modification principles". This group included patients who did not meet at least 2 dietary and/or physical level criteria.

The comparison of children with and without observed BMI reduction does not include those children with normal initial body weight. In the group of patients with BMI reduction, significantly lower levels of ALT, GGT and APRI at the endpoint were found. In spite of the lack of weight reduction, a decline in ALT level was also observed in the latter group. A comparison of both groups is provided in Table II.

Abnormal ALT level was observed in 25/49 children. In the group of children with increased ALT level, significant reduction of ALT, AST and GGT level was found with regard to baseline values (Table III). There was also a significant decline in mean APRI level and PLT count.

A statistically significant decrease in ALT and GGT level was found in the group with a reduction in BMI (respectively p=0.0028 and p=0.044, Figure 1). Furthermore, in the group with increased initial ALT, higher initial APRI values (0.52±0.28 vs. 0.29±0.20; p=0.002) were observed (Table III).

The decline in ALT level was negatively related to PNFS (r=−0.61; p<0.05; Figure 2a), APRI (r=−0.45; p<0.05; Figure 2b) and GGT level (r=−0.41; p<0.05; Figure 2c).

BMI: Body mass index, ALT: Alanine aminotransferase, AST: Aspartate aminotransferase, GGT: Gamma-glutamyltransferase, APRI: AST to Platelet Ratio index, PLT: Platelet
**Discussion**

According to the well-known regularity, NAFLD affects the vast majority of children with excessive body mass (13). In the described study group, all children were Caucasians. Most of them were boys, which aligns with previously published works (14). Suspicion of NAFLD in children is usually based on increased level of aminotransferases, especially ALT. According to studies, in obese and overweight children, elevated liver function tests have a sensitivity of 88% and specificity of 26% (15). In the study population, just over half of the children (51%) had slightly elevated liver function tests at baseline.

![Figure 1](image1.png)

**Figure 2.** Correlation between the decrease in ALT level and PNFS (a), APRI (b), and GGT level (c)

ALT: Alanine aminotransferase, PNFS: Pediatric NAFLD fibrosis score, APRI: Aspartate aminotransferase to platelet ratio index, GGT: Gamma-glutamyltransferase
Lifestyle modification plays a crucial role in the treatment of patients with NAFLD. Weight reduction of around 10% of the initial values is usually associated with an improvement in the markers of liver injury (16,17). The value of ALT decline as a marker of histological improvement, and thus, the effectiveness of NAFLD treatment has been confirmed in the past (18). In our research group, due to the ongoing growth of our patients, weight reduction was not observed. However, patients with a decrease in BMI at the end of the observation showed significantly lower ALT levels. Furthermore, even partial compliance to lifestyle modification without weight reduction resulted in a decline in ALT level.

The Mediterranean diet is usually considered as a recommended nutritional intervention in children and adults (19-22). In our study, this type of diet was recommended, resulting in a reduction of BMI and an improvement in biochemical parameters in a significant proportion of described patients (19). Compliance with dietary recommendations and lifestyle changes were assessed by the parents as being quite challenging to implement in their children’s lives. Due to the inconvenience and fear of poor cooperation, the complete quantitative assessment of diet compliance (e.g. weighing portions) was abandoned. The medical history and the general analysis of the menu were considered a reliable source of information.

Given the observed association of ALT level with a decrease in BMI in the research group, the AASLD recommendations for biannual screening with serum ALT in obese children and BMI in the 85th-94th percentile and other risk factors seem to be appropriate (3,23).

Elevated BMI is an independent factor that increases the risk of liver fibrosis. According to the studies of Iacobellis et al. (24), the significant upper limit of BMI above which the risk of fibrosis increases is 26.3 [odds ratio: 5.85, 95% confidence interval (CI): 1.6-21]. In the analysis of the presented research group, a decrease in ALT level was negatively related to PNFS and APRI. The PNFS index has an area under the receiver operating characteristic (AUROC) value of 0.74 for advanced fibrosis, the highest among non-invasive fibrosis indicators tested in children so far. Therefore, its relation to improving the health of patients who underwent lifestyle modification was emphasized.

Out of AST/ALT ratio, APRI, PNFS, and FIB-4 fibrosis scores as markers of hepatic fibrosis in children with NAFLD, APRI was characterized by high efficacy in the diagnosis without distinguishing the advancement of the process (25). In the results of our research, the negative correlation between the decrease in ALT level and the APRI value was statistically significant. Higher initial values of parameters indicating liver injury are not a factor reducing the effectiveness of lifestyle modifications in improving the clinical status of children with NAFLD. Interestingly, lower PLT count at the end of the observation period was observed in the group of patients with ALT decline. The reason for the higher initial PLT count may be chronic inflammation and oxidative stress resulting from obesity or iron deficiency in this group of patients (26).

A negative correlation between the decrease in ALT level and GGT was found in our study. According to previous reports, advanced fibrosis can be correlated with high GGT level. The level of this enzyme >45 IU/L had AUROC 0.65
Lifestyle Changes and Aminotransferases in Pediatric NAFLD

Malecki et al.

Study Limitations

The limitations of this study include the lack of a control group of overweight children without NAFLD undergoing lifestyle modification. It was also challenging to assess patient involvement in diet and exercise recommendations. The analysis did not include the histopathological assessment of liver tissue due to the small number of patients who underwent liver biopsy.

Conclusions

Lifestyle modification has a significant effect on the decrease in aminotransferase levels, even in those children who fail to achieve weight loss.

Changes in diet and physical exercise have a positive effect on improving the parameters of liver function regardless of their pre-lifestyle modification values.

Ethics

Ethics Committee Approval: The study design was approved by the Bioethics Committee of the Poznan University of Medical Sciences (no: 1074/17 of 9th November 2017).

Informed Consent: Informed consent was obtained from each patient included in the study.

Peer-review: Externally and internally peer-reviewed.

Authorship Contributions

Conflict of Interest: None of the authors had conflict of interest.

Financial Disclosure: The authors declared that this study received no financial support.
