Abstract
Herein, we report a case of a large and complex seminal vesicle cyst causing urinary retention in a young patient with left renal agenesis, psychotic disorder, and deep venous thrombosis. Abdominal computed tomography showed left renal agenesis with associated incipient hydronephrosis of the right renal unit. Furthermore, the whole pelvis was occupied by a large, heterodense cyst (116x113x107 mm), with several adherent and small cystic lesions (39x70 mm), compressing the posterior bladder wall. Open surgical approach was performed, including bilateral vesiculectomy with resection of the vas deferentia, since these structures were closely adhering to the cystic wall, and there was no clear surgical plane between them. A brief review of the literature on the main surgical options and postoperative outcomes was also undertaken.
Keywords: Zinner syndrome, seminal vesicle cyst, surgical treatment

Introduction
Zinner syndrome is a congenital anomaly comprising renal agenesis, seminal vesicle cysts, and ejaculatory duct obstruction (1,2). In symptomatic cases, patients may complain of lower urinary tract symptoms, including epididymitis and post-ejaculation pain. These symptoms are reported in approximately 30% of patients and usually related to the mass effect of the cyst during sexual activities (1-4). Conservative treatment is usually feasible for most cases; however, minimally invasive procedures may be considered as well (5,6). In challenging cases, surgical resection of the cyst by laparoscopic or open surgery may be necessary. Open surgery has been the preferred approach for many decades since good postoperative results have been reported for the preservation of genital structures. Moreover, a lower abdominal midline incision provides excellent tissue exposure, and it remains the most suitable approach in patients with large seminal vesicle cysts (4). Despite its advantages, open excision may be associated with injuries to pelvic organs such as the rectum, bladder, and pelvic ureter or formation of urinoma (7).

The current literature presented only a few cases of complex cystic lesions with invasion of surrounding structures, impeding fertility after surgical treatment. Herein, we present the radical surgical treatment of a unique case of complex, large, and infiltrative seminal vesicle cyst in a patient with Zinner syndrome, describing an unusual approach in a young, sexually active patient.

Case Reports
A 34-year-old Caucasian man, without children, was referred to our clinic in October 2020 for urodynamic testing following an episode of acute urinary retention. Before referral to our institution, the report of his previous urologist was unremarkable, except for noting a distended bladder. The patient complained of dysuria and perineal discomfort for 2 weeks, without fever or any other symptoms. His left renal agenesis was diagnosed many years ago by computed tomography (CT). He also had experienced a few episodes of acute paranoid reaction, although he was presently in remission. The
physical examination was unremarkable, and the vas deferens was bilaterally palpable. During a digital rectal examination, an irregular, partially fluctuant and partially solid mass was palpated in the prostatic fossa, measuring approximately 10 cm in diameter; the mass was painless and had no clear borders to the surrounding structures.

Laboratory analyses of the mass showed high levels of D-dimer (>1000 µg/L) and creatinine (124 µmol/L). Urinalysis and other blood tests were unremarkable. On further investigation, Doppler ultrasonography of the lower extremity revealed old thrombotic masses within the common and superficial right femoral veins, with signs of recanalization. Abdominal CT confirmed left renal agenesis associated with incipient hydronephrosis of the right renal unit, with multiple ureteral “kinking” (Figure 1a). Furthermore, the whole pelvis was occupied by a large, heterodense cyst (116×113×107 mm), with several adherent and small cystic lesions (39×70 mm), which resembled a morphologically degenerated left seminal vesicle (Figure 1b). The cyst had compressed the posterior bladder wall, and its volume was reduced significantly (Figure 1c). The right seminal vesicle could not be clearly detected (confined within the cystic lesion), and the prostate appeared normal, as it was clearly defined and homogenous.

### Surgical Treatment

An open surgical approach was initiated, as conservative treatment was not an option. The patient was positioned supine, and a lower midline incision was made to allow for an extraperitoneal approach. After separating the rectus muscle fibers, a large cystic mass was identified, bulging from the wound deep within the pelvis (Figure 2a). The cyst was multilocular in its distal part, with no clear plane of dissection to the left seminal vesicle. Moreover, the vas deferens was adherent to the cystic wall bilaterally, without a clear surgical plane between these structures (Figure 2b). Although the cyst was completely separated from the prostate, further dissection from the ipsilateral seminal vesicle and vas deferens was unsuccessful because of the close proximity of these structures to the cystic membrane. Therefore, bilateral vesiculectomy with resection of the vas deferentia was inevitable (Figure 2c). In the early postoperative period, the patient developed repeated urinary retention, which was treated with Foley catheterization. Cystoscopy revealed increased bladder capacity (>1500 mL), without voiding desire, even after instillation of 1500 mL of sterile saline. In the following month, urodynamic testing revealed normal detrusor function, with no involuntary voiding. The final pathology report confirmed the diagnosis of a complex cyst with nodular steatonecrosis, but no signs of malignancy.
Discussion

Herein, we present an unusual congenital anomaly, which in most instances, is difficult to detect. Only a few cases have been reported in the literature, and most cases presented during the sexually active period of life, usually in association with infertility (1,8). According to Tan et al. (2), seminal vesicle cysts can be categorized into four groups, ranging from simple cysts treated by a transrectal or transperineal approach to potentially malignant lesions, which are best treated by an open surgical resection. Our case report presents a complex cyst, which was larger than 10 cm, was multilocular and heterodense on CT, and required surgical treatment. In addition, the indication for surgery was compressive effect of the mass on the bladder (2).

Observation management may be implemented in asymptomatic or slightly symptomatic cases (8). Therefore, even symptomatic cases may benefit from conservative management with intense follow-up if the ejaculatory duct is unobstructed and the ipsilateral testis remains normal (9). Invasive treatment should be restricted to challenging cases or patients whose treatment fails using conservative measures (6). A conservative transrectal aspiration, although easy to perform, is associated with a high risk of recurrence and infection and should not be repeated if ineffective (1). Laparoscopic or robotic approaches are preferred, since they provide the best results in terms of blood loss and hospital stay (10,11).

However, in this case, we performed bilateral open vesiculectomy and resected the vas deferentia without prior clinical confirmation of infertility. However, this was the only treatment option available, as a large, multilocular cystic lesion had involved both seminal vesicles, and a clear dissection plane was not possible. Moreover, this patient had a history of psychiatric disorders, which presented as an additional risk factor for infertility in the preoperative setting. Thus, we determined that partial vesiculectomy or other conservative approaches should not be considered in patients with large infiltrative cysts and unproven fertility, especially if any concern exists regarding the oncological safety and completeness of cystic resection. Finally, assisted reproduction may be offered to the patient with preserved testicular function.

This case points out the necessity of radical surgery in young male patients with Zinner syndrome accompanied by a large, complex, infiltrative seminal vesicle cyst despite its detrimental effect on potential fertility.
