**Objective:** We aimed to investigate the mastoid emissary vein (MEV) canal incidence and to identify its relationship with jugular bulb (JB) and sigmoid sulcus anatomical variations.

**Methods:** We retrospectively reviewed 1,300 patients with temporal bone computed tomography (CT) scans in January 2016 to March 2020. The presence and the diameter of the MEV canal, and the anatomical variations of the sigmoid sulcus and the JB were reviewed by two radiologists. High riding JB, JB diverticulum, dehiscence JB, and anterior and lateral protrusion of the sigmoid sulcus were evaluated. All variables were summarized using descriptive statistics. The differences between the groups for categorical data were investigated using the chi-square test. Numeric variables were compared with the Mann-Whitney and the Kruskal-Wallis tests. Logistic regression models were constructed.

**Results:** The study included 1,269 patients of whom 694 were female (54.7%) and 575 were male (45.3%). Their mean age was 39.01±18.47. Among them 915 (72.1%) had the right and 871 (68.6%) had the left MEV canal. Men were more likely to have the MEV canal on both sides. The presence of the right and left MEV canals was associated with the ipsilateral dominant JB/sigmoid sulcus. The left MEV canal was associated with the left high riding JB and right dehiscence JB.

**Conclusion:** This is the largest patient population reported in the literature and allows a more precise estimate of the MEV canal incidence. We also classified the diameter of the MEV canal to identify clinically relevant, prominent MEV incidence. This is also the first study to demonstrate a relationship between the presence of the MEV canal, and the JB and sigmoid canal variations. Since both the prominent MEV and the JB variations may be symptomatic, knowing this association between them may have clinical relevance.

## Introduction

The sigmoid sinus begins at the junction of the transverse sinus and the superior petrosal sinus and runs inferiorly to communicate with the internal jugular vein (IJV). The jugular bulb (JB) located in the jugular fossa and connects to the IJV (1). Developmental abnormalities of the sigmoid canal and the JB have been proven to be clinically relevant, and may present with tinnitus, vertigo, and hearing loss (2).

While the IJV is the major extracranial venous drainage path, especially in prone position, the posterior fossa emissary veins are the primary route in upright position (3). The posterior fossa emissary veins connect the sigmoid sinus with the extracranial veins. The morphology of the posterior fossa dural sinuses, the emissary veins, and the JB are associated with the development of the brain, the shift to the postnatal type of circulation, and the postural hemodynamic change (1, 4). Regarding this close relationship, variations of the sigmoid sinus, the JB and the posterior fossa emissary veins may be associated.

A mastoid emissary vein (MEV) is a posterior fossa emissary vein that connects the sigmoid sinus and the posterior auricular or occipital vein crossing the mastoid foramen (4). Recognizing the MEV preoperatively is important. Because it may be a significant source of bleeding during skull base or middle ear surgery, detailed anatomical knowledge may prevent such complications (4). Air embolism may occur as a postoperative complication during a lateral suboccipital approach. Surgical materials used for hemostasis of the MEV may also cause complications (5).

The MEV may be the major drainage pathway to the extracranial venous system in the case of variations of dural sinuses or dural arteriovenous fistulas. It may also be used as an access route for the endovascular treatment of dural arteriovenous fistulas (6). The MEV may cause thrombosis of the sigmoid sinus after surgery of the middle ear. In addition, when the MEV is the major venous drainage of the posterior fossa, its ligation may result in venous ischemia and hemorrhage. Thrombosis of the MEV may occur as a complication of acute otomastoiditis. MEVs may also be a pathway for the spread of infections (7). Large MEVs may cause pulsatile tinnitus like JB and sigmoid sulcus variations (8).

MEVs can be evaluated with temporal bone computed tomography (CT) scan, CT angiography and magnetic resonance (MR) venography (8). Temporal CT scan and CT angiography are valuable tools for assessing the emissary veins and the venous vascular canals and are superior to MR venography in depicting venous structures with slower flow and smaller diameters (9, 10).

We evaluated the MEV canal incidence in a large patient population and to investigate their relationship with JB and

sigmoid sulcus anatomical variations using temporal bone CT scans.

## Methods

### Patients

This retrospective study was approved by the İzmir Health Sciences University, Tepecik Training and Research Hospital Ethics Committee (2020/14-66), and written informed consent was waived. In January 2016 to March 2020, we retrospectively reviewed 1,300 patients with temporal bone CT scans available at our department.

We excluded patients with previous mastoid, skull base, or posterior fossa surgery, dural sinus thrombosis or vascular malformations. Patients with poor technique or motion artifacts, and whose anatomy could not be properly assessed were excluded. We also excluded patients younger than five years old, since the JB may not be completely developed (10). Consequently, thirty-one patients were excluded, and 1,269 patients were included the study.

### CT Examination

All temporal CT examinations were obtained using a 128-slice CT scanner (SOMATOM Definition AS, Siemens Healthcare, Erlangen, Germany) with a standard protocol without contrast administration. The scanning parameters included: detector collimation widths 128x0.6 mm, tube voltage of 120 kV. Patients were scanned in the caudal to cranial direction with a scan revolution time of 1 second and pitch of 0.8. Tube current was regulated by an automatic exposure control system (CARE Dose 4D; Siemens, Erlangen, Germany). Images were reconstructed in axial, coronal, and sagittal planes with a slice thickness of 1 mm. The images were transmitted to the picture archiving and communication systems (PACS).

### Image Analysis

The anatomical variations in the MEV, sigmoid sulcus, and JB were evaluated on 0.6 mm slice thickness images that were transmitted from PACS to the workstation (Aquarius Workstation; TeraRecon, San Mateo, California, USA). The images were evaluated on this workstation, in the axial, coronal, and sagittal planes by two radiologists, A.A. and R.P. (with 4 and 15 years of experience, respectively).

The MEV canal runs from the sigmoid sulcus extracranially, crossing the mastoid foramen. The presence of the MEV canal was noted and classified according to its size: less than 2 mm, between 2 and 5 mm, and more than 5 mm (Figure 1).

Developmental abnormalities of the JB (high riding JB, JB diverticulum, dehiscent JB), and variations of the sigmoid sulcus (anterior and lateral protrusion) were evaluated.

When the roof of the JB was at the same level or above the floor of the internal acoustic canal, it was defined as high riding JB (Figure 2). A dehiscent JB was considered when the bony plate of the protruding JB toward the middle ear cavity was absent. Jugular bulb diverticulum was considered when there was an outpouching from the JB (11, 12) (Figure 3).

Sigmoid sulcus variation was characterized by an anterior and lateral position of the sigmoid sulcus in the mastoid bone (10, 13) (Figure 4). When the distance between the sigmoid sulcus lateral wall and the external tabula of the temporal bone was less than 2 mm, and the distance between the sigmoid sulcus anterior wall and the external acoustic canal was less than 2 mm, it was considered as a bulge of the sigmoid sulcus. The measurements were made on the axial images that showed the entire lateral semicircular canal.

Sigmoid sulcus/JB dominance was classified as right, left, or bilateral, according to the prominent vascular sulcus/bulb on one or both sides.

### Statistics

IBM SPSS 23.0 statistical packages were used in statistical analysis. All variables were summarized with descriptive

statistics. For some comparisons between different groups, the Kolmogorov-Smirnov Goodness-of-Fit test was used to investigate numerical variables to identify whether their distributions were parametric or non-parametric. The differences between groups for categorical data were investigated using the chi-square test, while the numerical variables between different groups were compared to each other with Mann-Whitney U test in two labeled classes and the Kruskal-Wallis test in three or more labeled groups. Further statistical methods, logistic regression models were constructed for the right and the left MEV canals. The binary logistic regression models were explained and compared to each other with accuracy scores, odds ratios, and significances of some important independent variables. The models were also visualized using Receiver Operating Characteristic (ROC) graphics.  $p < 0.05$  was considered

statistically significant. An inter-observer reliability analysis with the kappa statistic was performed, and intraclass correlation coefficient (ICC) scores with 95% CIs were calculated.

### Results

After the initial screening, 1,269 patients, 694 females (54.7%) and 575 males (45.3%) with a mean age of 39.01±18.47 were included in the study. Descriptive findings are given in Table 1.

We did not have any patients with the MEV canal larger than 5 mm. In our study population, 915 patients (72.1%) had a right MEV canal, and 871 patients (68.6%) had a

left MEV canal. Among all, 334 (26.3%) of the right MEV canals and 291 (22.9%) of the left MEV canals were larger than 2 millimeters.

Table 2 shows the mean age of the patients with right and left MEV canals. Comparison of patients by age showed no difference between the right (p=0.063) and the left MEV canals (p=0.367).

The frequency of the right and the left MEV canals in males and females are demonstrated in Table 3. MEV canals with a 2-5 mm diameter were less frequent in female patients (p=0.002 and p<0.001, respectively).

The frequencies and percentages of the right and the left MEV canals by the existence of other variables are demonstrated in Tables 4 and 5. There was no relationship between the presence of a right MEV canal and JB or sigmoid sulcus

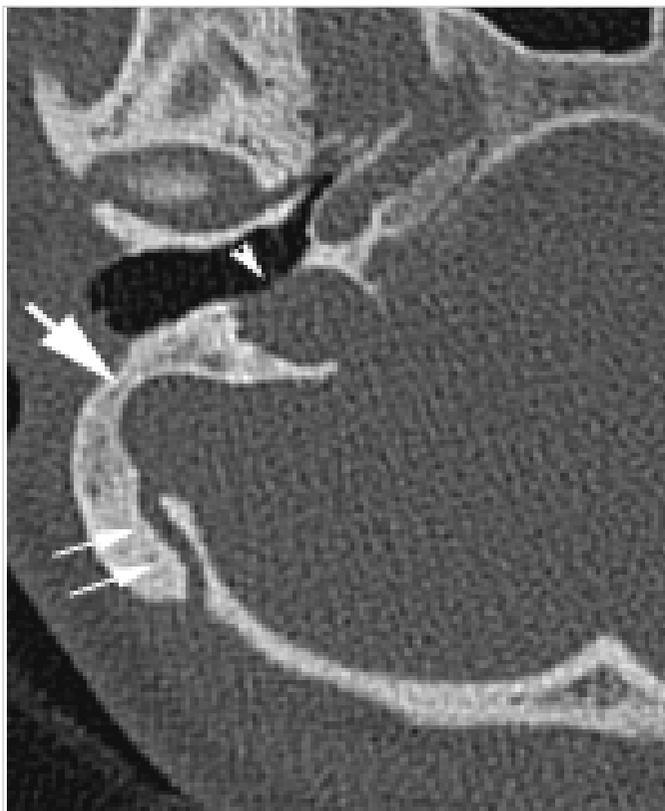

Figure 4. Temporal CT axial reformatted image shows lateral protrusion of the sigmoid sulcus into the mastoid bone (arrow). There is also a small (<2 mm) mastoid emissary vein canal (double arrow) and dehiscent jugular bulb (arrowhead)

MEV: Mastoid emissary vein, \*determined by the jugular bulb/fossa and sigmoid sulcus diameter, f: frequency of MEV canals

According to the logistic regression model, males were 1.3 times more likely to have a left MEV canal than females. Males were 1.88 times more likely to have a 2-5 mm left MEV canal than females. Further, patients with a left high riding JB were 1.59 times more likely to have a 2-5 mm left MEV canal.

Inter-observer agreement for the evaluation of the variations was excellent, with an ICC score ranging from 0.91 to 0.95 (95% CI).

### Discussion

We evaluated MEV canal incidences and JB and sigmoid sulcus variations in 1,269 patients. While the presence

of a MEV canal was not found associated with age, males were more likely to have MEV on both sides in this large patient group. Regarding the closely related developmental factors between the dural sinuses and the emissary veins of the posterior fossa and the JB, we expected that the variations of the sigmoid sinus, the JB and the MEV could be associated (1). The presence of a right or a left MEV canal was associated with the prominent JB/sigmoid sulcus, ipsilaterally ( $p=0.003$ ). Although a right MEV canal was not related to JB or sigmoid sulcus variations, a left MEV was associated with a left high riding JB ( $p=0.014$ ) and a right dehiscence JB ( $p=0.006$ ). Patients with a left high riding JB were more likely to have a prominent left MEV in our study. Both the prominent MEV and the JB variations may be symptomatic and cause tinnitus as described by Kizildag et al. (10); thus, knowing this association may have clinical relevance.

Given its high spatial resolution, temporal bone CT scan is a valuable tool for assessing the temporal bone anatomy. It allows visualizing the fine anatomic structures of the middle and inner ears. The presence and variations of posterior fossa vascular canals can also be easily evaluated with temporal bone CT scans. With the introduction of multidetector techniques, images of less than 1 mm in diameter with multiplanar reformation improved diagnostic accuracy in the evaluation of the submillimetric structures (9). Brain CT angiography is also a valuable tool for assessing emissary veins. It allows to evaluate both emissary veins and dural venous sinuses (14). It is superior to MR venography in depicting venous structures with slower flow and smaller diameters (15). The major advantage of MR venography is lack of ionizing radiation.

In our study, the frequency of a right MEV, both <2mm and 2-5 mm, was slightly higher (72.1%) than that of a left MEV (68.6%). Frequency of MEV in cadaveric and imaging studies are reported within a wide range, mostly because of the number of patients and the methods used. Whether the MEV canal is more common on the right or on the left side is also controversial. A cadaveric study described a MEV in 63% of 12 specimens (3). Louis et al. (5) reported a MEV prevalence of 98% on the right and of 72% on the left side in their cadaveric study of 200 specimens. Reis et al. (16) reported MEV in 89% of their specimens. Koesling et al. (11) described the MEV canal incidence as 82% using high-resolution CT imaging. Pekçevik et al. (14), using CT angiography, identified MEV in 77.7% of their 166 patients, and more commonly on the left side. In their study using MR venography, Gulmez Cakmak et al. (15) found the MEV prevalence as 82.7% on the right side and as 81.4% on the left side in 247 patients. Tsutsumi et al. (17), using MRI, described the MEV incidence as 89.5%, 51.8% on the right and 24.7% on the left side. The relatively high incidence of right MEV, in our study and most of the other studies in the

literature, may be related to the similar mechanisms that are suggested to be the cause of the right JB and sigmoid sulcus dominance (1).

The major advantage of our study is that it is the largest patient population reported in the literature and allows a more precise estimate of the MEV canal incidence.

We also classified the MEV canals according to their diameter, especially to find the incidence of large-sized MEVs. There is no classification for the MEV canal in the literature. Previous studies only reported about the incidence of the MEV and did not classify these veins according to their diameter. We classified the MEV canal in our study, first to search for whether the relationship with JB and sigmoid sulcus variations is related to the diameter of the MEV, and second to find the incidence of a large MEV canal. Recognizing prominent mastoid emissary veins may have clinical significance.

A large MEV may cause bleeding during the skull base or middle ear surgery (4). Air embolism or embolism of the surgical material that are used to achieve hemostasis of the MEV may occur (5). Emissary veins may be prominent in patients with high-flow vascular malformations and hypoplasia or aplasia of the jugular veins. A large MEV may be a potential target for cannulation during endovascular procedures involving the transverse or sigmoid sinus (6).

In our study, the MEV canal was accepted as prominent when larger than 2 mm. We found the MEV canal prominent in 334 patients (26.3%) on the right and 291 patients (22.9%) on the left. Koesling et al. (11) described the MEV canal as prominent when larger than 1 mm, and found this in 6% of the patients in their study. This is significantly lower compared to our study and may be due to either the CT image resolution or a lesser number of patients.

Enlarged posterior fossa emissary veins were found to be associated with craniofacial syndromes (18). Sarioglu et al. (19) found prominent MEV, larger than 2 mm, more commonly in cochlear implant candidates (19.11%) compared to the control group (6.3%) in pediatric patients. Our study included both adult and pediatric patients older than 5 years old.

The presence of the MEV canal was not related to age in our study. Although the reason is not clear, males were more likely to have MEV on both sides than females in our large patient group. Louis et al. (5) found no relationship between gender or age. Gulmez Cakmak et al. (15) described the left MEV diameter higher in males, while Lang and Samii (20) observed that the MEV canal was less frequent in females. Dural venous sinus anomalies may also show gender differences like those in MEV. Hypoplasia of the left transverse sinus was reported to be more common in males (21). This may also give a clue about the relationship between

the presence of the MEV and the JB and sigmoid sulcus variations.

The sigmoid sinus and jugular sinus, primitive JB, occur at a similar period in the fetus. The MEV vein originates from the ipsilateral sigmoid sinus and communicates with the extracranial veins (1, 4). Enlargement of the jugular sinus for becoming a JB is a dynamic process and not present at birth. It occurs after two years. Standing upright (rather than the horizontal position maintained in the in-utero and neonatal periods) causes an upward negative pressure generating from the heart to strike the jugular sinus at the jugular foramen. This results in bulbous enlargement of the primitive JB and sigmoid sinus. It is suggested that the relatively long left brachiocephalic vein may cause the dissipation of the energy transmitted to the left primitive JB. This may contribute to the higher incidence of large right JB and sigmoid sinus (1, 4). We identified an association between the dominant sigmoid sulcus/JB and the presence of the ipsilateral MEV. This may be due to the postural hemodynamic change that affects the morphology of the JB, dural sinuses and emissary veins of the posterior fossa at the same time.

Although we did not find any relationship between the presence of a right MEV and JB or sigmoid sulcus variations, a left MEV was associated with the existence of left high riding JB ( $p=0.014$ ) and right dehiscent JB ( $p=0.006$ ). In our study, patients with left high riding JB were more likely to have a 2-5 mm left MEV. This relationship between a prominent left MEV and a high riding JB was not described previously. This is the first study to demonstrate the relationship between the presence of a MEV canal and JB and sigmoid canal variations. Both the prominent MEV and the high riding JB may be symptomatic and cause tinnitus (8). Knowing this relation may be clinically important. Gulmez Cakmak et al. (15) described an association between the presence of the MEV and variations of the transverse sinus, especially hypoplasia and aplasia of the transverse sinus, on the left side using MR venography. These findings are supported by the strong relationship between the embryological development of the posterior fossa emissary veins and dural venous sinuses (1). Although this study used MR venography to evaluate the MEV and dural venous sinuses, the findings support our hypothesis.

Our study also has some limitations. It is a retrospective study and we evaluated non-contrast CT images. The depiction of very small emissary veins, which is beyond the capability of the CT examinations, could have been missed. We evaluated the MEV in our study. Other posterior fossa emissary canals were not evaluated, since the MEV is considered as the most clinically important posterior fossa emissary vein and expected to show an association with the JB and sigmoid sulcus variations.

In conclusion, we evaluated the MEV canal incidence as well as JB and sigmoid sulcus variations. This is the largest patient population in the literature and allows for a more precise estimate of the MEV canal incidence. We also classified the diameter of the MEV canal to identify clinically relevant prominent MEV incidences. This is the first study to demonstrate the relationship between the presence of a MEV canal and JB and sigmoid canal variations. The presence of right and left MEV canals were associated with a prominent JB/sigmoid sulcus on the same side. A left MEV was associated with a left high riding JB and a right dehiscent JB. Patients with left high riding JB were more likely to have a prominent left MEV. Since both the prominent MEV and the JB variations may be symptomatic, knowing the incidence and association between the MEV canal and JB or sigmoid sulcus variations may have clinical relevance.

**Ethics Committee Approval:** This retrospective study was approved by the institutional review board of İzmir Health Sciences University, Tepecik Training and Research Hospital) (approval no: 2020/ 14-66, date: 23/12/2020).

**Informed Consent:** Written informed consent was waived.

**Peer-review:** Externally peer-reviewed.

#### Main Points

- Developmental abnormalities of the sigmoid canal and jugular bulb (JB) have been proven to be clinically relevant, and can present with tinnitus, vertigo, and hearing loss.
- The mastoid emissary vein (MEV) is a posterior fossa emissary vein. It connects the sigmoid sinus and posterior auricular or occipital vein. Recognizing the MEV is clinically important.
- Presence of both right and left MEVs was associated with the ipsilateral prominent JB/sigmoid sulcus.
- The left MEV was associated with left high riding JB and right dehiscent JB. Patients with left high riding JB were more likely to have a prominent left MEV.
- Both prominent MEV and JB variations may be symptomatic and knowing this association may have clinical relevance.
